THIRD EDITION REWRITTEN

NEW YORK : JOHN WILEY & SONS, INC.
LONDON : CHAPMAN & HALL, LIMITED
1936

PUBLISHER'S PREFACE

In making plans for new editions of our handbooks in mechanical engineering and in electrical engineering, it soon became clear that engineering science and practice had developed to such an extent that handbooks were growing beyond all practical bounds. They had become both bulky and inconvenient and contained much duplicated material. In order to solve the problems presented by these conditions, the editors of our various handbooks were asked to serve as an advisory editorial board.

This board recommended, first, that the fundamental material underlying all engineering be published in a separate volume, and, second, that the existing handbooks as they are revised be issued in several volumes containing material closely related to the specialized branches of engineering. As a result of these recommendations, the Wiley Engineering Handbook Series has been initiated, which in the beginning will comprise the following: Eshbach's "Handbook of Engineering Fundamentals"; Kent's "Mechanical Engineers' Handbook" in two volumes, viz., "Power" and "Design and Shop Practice"; Pender's "Electrical Engineers' Handbook" in two volumes, viz., "Electric Power" and "Communication and Electronics."

This division has also made it possible to devote more space to the various topics so that the entire new series of handbooks contains more complete information on all topics than heretofore has been possible. It is our hope that this new plan will give engineers information that is more useful, more complete, and in more convenient form.

John Wiley & Sons, Inc.

LIST OF CONTRIBUTORS

R. F. Abele, B.S. in E.E., Engineer, Chas. E. Bedaux Co., New York, N. Y.—*Grounding of Circuits.*

E. W. Allen, Sales Engineer, Edison Storage Battery Division, Thos. A. Edison, Inc.—*Alkaline Type Storage Batteries.*

F. S. Bennett, M.E., Mechanical Engineer, Construction Engineering Dept., General Electric Co.—*Steam Power Stations.*

J. G. Brainerd, D.Sc. in E.E., Assistant Professor, Moore School of Electrical Engineering, University of Pennsylvania.—*Tables, Units, Conversion Factors.*

Franklyn Brehme, formerly with Thos. A. Edison, Inc.—*Alkaline Storage Batteries.*

H. B. Brooks, M.E. in E.E., Ph.D., Chief, Electrical Instrument Section, National Bureau of Standards.—*Measurements and Measuring Apparatus.* Dr. Brooks was assisted by the following members of the Scientific Staff, National Bureau of Standards.

- **Donald B. Brooks,** Engineer, Automotive Section.
- **F. M. Defandorf,** Ph.D., Member, Electrical Instrument Section.
- **F. K. Harris,** Ph.D., Member, Electrical Instrument Section.
- **A. B. Lewis,** Ph.D., Member, Electrical Instrument Section.
- **J. F. Meyer,** Ph.D., Chief, Photometric Section.
- **R. L. Sanford,** Chief, Magnetic Measurements Section.
- **F. B. Silsbee,** Ph.D., Alternate Chief, Electrical Instrument Section.
- **H. T. Wensel,** Ph.D., Chief, Pyrometry Section.

C. F. Burgess, D.Sc., Chairman of C. F. Burgess Laboratories, Inc., Burgess Battery Co., Burgess Cellulose Co., Burgess-Parr Co.—*Primary Batteries.*

F. C. Caldwell, A.B., M.E. in E.E., Professor of Electrical Engineering, The Ohio State University.—*Lighting.*

Carl C. Chambers, D.Sc., in E.E., Instructor, Moore School of Electrical Engineering, University of Pennsylvania.—*Mathematics, Units and Conversion Factors.*

Herbert Chase, M.E., Consultant and Journalist, formerly Engineering Editor of Automotive Industries and Automotive Daily News and former Associate Editor of Product Engineering and American Machinist. Member and former officer of S.A.E.—*Automobiles, Internal Combustion.*

Alan. G. Cherry, Hydraulic Consultant and Contracting Engineer, M. H. Treadwell Co., Engineers, New York, N. Y.—*Hydroelectric Power Stations.*

H. A. Currie (deceased), late Electrical Engineer, New York Central System.—*Railways.*

W. A. Del Mar, A.C.G.I., Fellow A.I.E.E., Chief Engineer, Habirshaw Cable and Wire Corp. Division of Phelps Dodge Copper Products Corp.—*Power Transmission and Distribution. Associate Editor-in-Chief.*

H. A. Enos, B.S. in E.E., Member A.I.E.E., Distribution Engineer, American Gas & Electric Co.—*Pole and Tower Lines.*

C. J. Fay, B.S. in E.E., Engineer, Heating Engineering Dept., Westinghouse Elec. & Mfg. Co.—*Water Heating.*

Stephen Q. Hayes, A.B. and E.E. (deceased).—*Switching, Control and Protection.*

A. Dexter Hinckley, A.B. and E.E., Instructor, Dept. of Electrical Engineering, Columbia University.—*Resistors and Reactors.*

H. M. Hobart, M. Inst. C.E., Consulting Engineer, General Electric Co.—*Welding.*

Raymond A. Hopkins, B.S. in E.E. and E.E., Principal Electrical Engineer, Tennessee Valley Authority.—*Hydroelectric Power Stations and Station Wiring.*

Wm. P. Kennedy, Consulting Transportation Engineer, New York, N. Y. Member A.S.M.E., A.I.E.E., S.A.E. (Closely identified with application of electric vehicles in large fleets since inception.)—*Electric Automobiles.*

Martin Kilpatrick, Ph.D., Assistant Professor of Chemistry, University of Pennsylvania.—*Principles of Electrochemistry.*

Mary Kilpatrick, Ph.D.—*Principles of Electrochemistry.*

Knox McIlwain, B.S. and E.E., Assistant Professor, Moore School of Electrical Engineering, University of Pennsylvania.—*Assistant Editor-in-Chief.*

Douglas F. Miner, A.B., B.S. and E.E., Manager, Material and Process Engineering Dept., Westinghouse Elec. & Mfg. Co.—*Materials.*

John H. Palmer, E.E., Research Engineer, Habirshaw Cable & Wire Corp. Division of Phelps Dodge Copper Products Corp.—*Stability of Circuits.*

Harold Pender, Ph.D. and Sc.D. (Hon.), Dean, Moore School of Electrical Engineering, University of Pennsylvania. Past Vice-President of A.I.E.E.—*Editor-in-Chief.*

Lee C. Prickett, B.Sc. Agriculture, Agricultural Industries Division, Tennessee Valley Authority.—*Agriculture.*

J. H. Reifenberg, B.S. in M.E., Engineer, Appliance Engineering Dept., Westinghouse Elec. & Mfg. Co.—*Water Heating.*

Robert S. Rhodes, Assistant Engineer, New York Central System.—*Railways.*

W. I. Slichter, E.E., Professor of Electrical Engineering and Head of Dept., Columbia University.—*Motors, Generators, Transformers, Converters and Rectifiers, Substations.*

Wm. Allan Sloan, Professor of Mechanical Engineering, University of Pennsylvania.—*Internal Combustion Power Stations.*

N. W. Sultzer, Sales Engineer, Research Corp., New York, N. Y.—*Electrostatic Precipitation.*

M. deK. Thompson, Professor, Dept. of Mining and Metallurgy, Massachusetts Institute of Technology.—*Electrochemical Processes.*

Frank Thornton, Jr., B.S. in E.E., Engineering Manager, Association Activities, Westinghouse Elec. & Mfg. Co.—*Household Heating and Cooking.*

Irven Travis, M.S. in E.E., Assistant Professor, Moore School of Electrical Engineering, University of Pennsylvania.—*Electric Theory.*

Otto W. Walter (deceased), late Assistant Professor of Electrical Engineering, The College of the City of New York.—*Heating and Air Conditioning of Buildings.*

W. O. Wentworth, Assistant Engineer, New York Central System.—*Railways.*

Francis A. Westbrook, M.E., Consulting Engineer, Center Conway, N. H. (Industrial Power Specialist).—*Industrial Applications of Motors.*

J. Lester Woodbridge, B.S., M.E. and Eng. Dr., Chief Engineer, The Electric Storage Battery Co.—*Lead Acid Storage Batteries.*

George W. Zink, M.E., Assistant Engineer, Habirshaw Cable & Wire Corp. Division of Phelps Dodge Copper Products Corp.—*Wiring of Buildings.*

W. N. Zippler, B.S. and E.E., Electrical Engineer, Gibbs & Cox, Inc., Naval Architects, Secretary Marine Committee of A.I.E.E.—*Electric Propulsion of Ships.*

GENERAL TABLE OF CONTENTS

Detailed tables of contents are given at the beginning of each section. An alphabetical index appears following Section 19.

SECTION 1. MATHEMATICS, UNITS, AND SYMBOLS

	PAGE
Mathematics	1-02
Mathematical Tables	1-18
Units and Conversion Factors	1-36
Symbols and Abbreviations	1-64
Constants	1-70

SECTION 2. PROPERTIES OF MATERIALS

Weights of Materials	2-02
Conductor Materials	2-05
Insulating Materials	2-12
Magnetic Materials	2-38
Thermal Properties of Materials	2-49

SECTION 3. ELECTRIC CIRCUITS AND ELECTRIC LINES

Alternating Currents	3-02
Linear Circuits	3-09
Non-linear Circuits	3-19
Polyphase Systems and Symmetrical Components	3-29
Electrical Machines	3-41
Transmission Lines	3-45
Stability of Power Systems	3-49

SECTION 4. RESISTORS, REACTORS, MAGNETS

Resistors, Rheostats	4-02
Capacitors—Condensers	4-08
Inductors	4-16
Magnets, Magnetic Devices	4-26

SECTION 5. MEASUREMENTS AND MEASURING APPARATUS

SECTION 6. PRINCIPLES OF ELECTROCHEMISTRY

SECTION 7. BATTERIES

Primary Batteries	7-02
Lead-acid Storage Batteries	7-08
Alkaline-type Storage Batteries	7-24

SECTION 8. DIRECT-CURRENT MACHINES

Direct-current Generators	8-02
Direct-current Motors	8-30

SECTION 9. ALTERNATING-CURRENT MACHINES

Alternating-current Generators	9-02
Synchronous Motors	9-28
Polyphase Induction Motors	9-36
Single-phase Induction Motors	9-58
Alternating-current Commutator Motors	9-60

SECTION 10. TRANSFORMERS

SECTION 11. CONVERTERS AND RECTIFIERS

Energy Converters	11-02
Frequency Converters	11-13
Phase Converters and Balancers	11-17
Rectifiers	11-18

SECTION 12. SWITCHING, CONTROL, AND PROTECTION

	PAGE
Circuit Elements	12-02
Circuit Breakers	12-11
Controllers and Regulators	12-29
Protection	12-42
Station Equipment	12-49
Station Structures and Layout	12-60

SECTION 13. POWER STATIONS AND SUBSTATIONS

Steam Power Stations	13-02
Hydroelectric Power Stations	13-14
Internal-combustion Power Stations	13-29
Substations	13-36
Power Station Circuits	13-46

SECTION 14. POWER TRANSMISSION AND DISTRIBUTION

Systems	14-03
Electrical Design of Transmission and Distribution Systems	14-12
Capacitance and Inductance Tables	14-37
Pole and Tower Lines	14-54
Underground Lines	14-119
Distribution	14-132
Bare Wires and Cables	14-143
Insulated Wires and Cables	14-171
Wiring of Buildings	14-226
Grounding of Electric Circuits and Accessories	14-258
Electrolysis of Underground Structures	14-267

SECTION 15. LIGHTING AND HEATING

Lighting	15-02
Household Heating Appliances and Cooking	15-44
Water Heating	15-46
Heating and Air Conditioning of Buildings	15-50

SECTION 16. INDUSTRIAL APPLICATIONS OF MOTORS

SECTION 17. TRANSPORTATION

Electric Traction	17-02
Electrical Equipment of Internal-combustion Automobiles	17-72
Electric Automobiles	17-101
Electric Propulsion of Ships	17-108

SECTION 18. ELECTROCHEMICAL AND ELECTROTHERMAL INDUSTRIES

Electrochemical Processes	18-02
Electric Furnaces and Their Products	18-12
Electric Resistance Heating	18-22
Electrical Precipitation of Suspended Particles	18-31
Electric Welding	18-34

SECTION 19. ELECTRICITY ON THE FARM

For contents of other handbooks of this series, see pages following Index of this volume.

This book is divided into sections, each section carrying its independent sequence of page numbers. For example, 3-15 indicates Section 3, page 15.

SECTION 1

MATHEMATICS, UNITS, AND SYMBOLS

MATHEMATICS

By Carl C. Chambers

1. Algebraic Formulas 02
2. Complex Quantities 06
3. Trigonometric Formulas 07
4. Exponential and Hyperbolic Formulas. 09
5. Calculus Formulas 12

MATHEMATICS

By Carl C. Chambers

1. ALGEBRAIC FORMULAS

MISCELLANEOUS FORMULAS

$$(a \pm b)^2 = a^2 \pm 2ab + b^2$$

$$(a \pm b)^3 = a^3 \pm 3a^2 b + 3ab^2 \pm b^3$$

$$(a \pm b)^n = \sum_{k=0}^{n} \frac{n!}{k!\,(n-k)!} a^k (\pm b)^{(n-k)}, \qquad n! = M(M-1)\ \ldots\ 3 \times 2 \times 1$$

$$a^2 - b^2 = (a+b)(a-b)$$

$$a^2 + b^2 = (a+jb)(a-jb), \quad j = \sqrt{-1}$$

$$a^x \times a^y = a^{(x+y)}, \quad a^\circ = 1 \text{ [for } a \neq 0], \quad (ab)^x = a^x b^x$$

$$\frac{a^x}{a^y} = a^{(x-y)}, \quad a^{-x} = \frac{1}{a^x}, \quad \left(\frac{a}{b}\right)^x = \frac{a^x}{b^x}$$

$$(a^x)^y = a^{xy}, \quad a^{1/x} = \sqrt[x]{a}, \quad \sqrt[x]{ab} = \sqrt[x]{a}\,\sqrt[x]{b}$$

$$\sqrt[x]{\sqrt[y]{a}} = \sqrt[xy]{a}, \quad a^{x/y} = \sqrt[y]{a^x}, \quad \sqrt[x]{\frac{a}{b}} = \frac{\sqrt[x]{a}}{\sqrt[x]{b}}$$

$$\log (a^x) = x \log a, \quad \log ab = \log a + \log b$$

$$\log \frac{a}{b} = \log a - \log b$$

$$\text{If } \frac{a}{b} = \frac{c}{d} \text{ then } \frac{a \pm b}{b} = \frac{c \pm d}{d} \text{ and } \frac{a-b}{a+b} = \frac{c-d}{c+d}$$

The sum of an arithmetical progression is given by

$$s = \frac{n}{2}(a + l) = \frac{n}{2}\{2a + (n-1)d\}$$

where $l = a + (n-1)d$ is the last term, a is the first term, d is the common difference, and s is the sum of the n terms.

The sum of a geometrical progression is given by

$$s = a\frac{(1-r^n)}{1-r} = \frac{lr - a}{r-1}$$

where $l = ar^{n-1}$ is the last term, a is the first term, d is the common ratio, and s is the sum of the n terms. If n approaches infinity and r^2 is less than unity

$$s = \frac{a}{1-r}$$

The multiple product represented by $n(n-1)(n-2)\ \ldots\ 3 \times 2 \times 1$ is designated by the symbol $n!$ or $\underline{|n}$ and is called "n factorial." The following list gives the value of n up to $n = 10$

1! =	1	6! =	720
2! =	2	7! =	5,040
3! =	6	8! =	40,320
4! =	24	9! =	362,880
5! =	120	10! =	3,628,800

For large values of n a good approximation for $n!$ is, from Stirling's formula,

$$n! = (2\pi n)^{1/2}\left(\frac{n}{e}\right)^n, \quad e = 2.7182818$$

This formula is accurate to about $2^1/_2$ per cent at $n = 10$ and becomes more accurate very rapidly as n is increased,

The number of permutations or arrangements of n things taken p at a time is

$$P_p^n = \frac{n!}{(n-p)!}$$

The number of combinations of n things taken p at a time is then

$$C_p^n = \frac{1}{p!} P_p^n$$

QUADRATIC EQUATION. The solution of

$$ax^2 + bx + c = 0$$

is

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

If a, b, and c are real, and the discriminant, $b^2 - 4ac$, is positive, the roots are real and unequal; if it is zero, the roots are real and equal; if it is negative, the roots are conjugate complex numbers.

CUBIC EQUATIONS. The solution of

$$ax^3 + 3bx^2 + 3cx + d = 0 \tag{1}$$

is obtained as follows: Put $x = \frac{1}{a}(y - b)$; then (1) becomes

$$y^3 - 3Hy + G = 0$$

where

$$H = b^2 - ac$$
$$G = a^2 d - 3abc + 2b^3$$

For a solution let

$$A = \sqrt[3]{\frac{-G}{2} + \sqrt{\frac{G^2}{4} - H^3}}, \quad B = \sqrt[3]{\frac{-G}{2} - \sqrt{\frac{G^2}{4} - H^3}}$$

then the values of y will be given by

$$y = A + B, \quad -\frac{1}{2}(A + B) + j\frac{\sqrt{3}}{2}(A - B), \quad -\frac{1}{2}(A + B) - j\frac{\sqrt{3}}{2}(A - B)$$

If a, b, c, d are real and if $G^2 - 4H^3$, the discriminant, is positive there are one real root and two conjugate complex roots; if $G^2 - 4H^3$ is zero there are three real roots, at least two of which are equal; if $G^2 - 4H^3$ is negative there are three real and unequal roots.

The solution may be written in three other forms.

(1) Put

$$\phi = \frac{1}{3}\sin^{-1}\left[\frac{G}{2H\sqrt{H}}\right]$$

then the roots are

$$y = 2\sqrt{H}\sin\phi, \quad 2\sqrt{H}\sin(\phi + 120°), \quad 2\sqrt{H}\sin(\phi - 120°)$$

Or (2) put

$$u = \frac{1}{3}\cosh^{-1}\left[\frac{G}{2H\sqrt{H}}\right]$$

then the roots are

$$y = -2\sqrt{H}\cosh u, \quad \sqrt{H}\cosh u + \sqrt{-3H}\sinh u, \quad \sqrt{H}\cosh u - \sqrt{-3H}\sinh u$$

Or (3) put

$$u = \frac{1}{3}\sinh^{-1}\left[\frac{G}{2H\sqrt{-H}}\right]$$

Then the roots are

$$y = 2\sqrt{-H}\sinh u, \quad -\sqrt{-H}\sinh u + \sqrt{3H}\cosh u$$
$$-\sqrt{-H}\sinh u - \sqrt{3H}\cosh u$$

SIMULTANEOUS EQUATIONS. Given n independent equations in n unknowns, these n equations usually fix one or more values for each of the n unknowns. To solve

such a set of simultaneous equations in x, y, and z, say, solve each of the three equations for x in terms of y and z. Equating these three values for x gives two equations in y and z. Solving each of these two equations for y in terms of z and equating these two values of y gives a single equation in z. The solution of this last equation then gives the value of z. Then substitute this value of z in either of the equations in y and z, and solve for y. Then substitute these values of y and z in any one of the original equations and solve for x.

DETERMINANTS. In the case of linear simultaneous equations (i.e., when x, y, and z occur only to the first power), the equations may be solved by determinants. This method is a considerable time-saver when the number of unknowns is greater than three, but when the number of unknowns is three or less the straight substitution method is preferable.

The determinant of a set of simultaneous equations is formed by writing the equations one below the other with the same unknown in the same relative position in each. The block of numbers forming the coefficients of the unknowns is called the determinant. For example, the determinant of the equations

$$\begin{aligned} w + x + y + z &= 6 \\ w + \phantom{2x+{}} y + 3z &= 4 \\ w + 2x + 3y \phantom{{}+z} &= 1 \\ w + 3x + \phantom{3y+{}} z &= 3 \end{aligned}$$

is

$$D = \begin{vmatrix} 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 3 \\ 1 & 2 & 3 & 0 \\ 1 & 3 & 0 & 1 \end{vmatrix}$$

The values of any one of the unknowns, say y, is found by writing a second determinant, D_y, exactly like the determinant D, except that the constants forming the right-hand members of these equations are substituted for the coefficients of y in the determinant, that is

$$D_y = \begin{vmatrix} 1 & 1 & 6 & 1 \\ 1 & 0 & 4 & 3 \\ 1 & 2 & 1 & 0 \\ 1 & 3 & 3 & 1 \end{vmatrix}$$

Then

$$y = \frac{D_y}{D}$$

and similarly for the other unknowns.

The value of any determinant is found by making use of the following rules:

(1) If a determinant has two equal rows or columns, it is equal to zero.

(2) To any row or column one may add or substract any number of times any other row or column without altering the value of the determinant.

(3) To multiply any row or column by a number is the same as multiplying the determinant by that number.

(4) If all the terms in a row or column except one are zero, the determinant reduces to one of a lower order which may be obtained by striking out the row and column which intersect at the element of the row or column which is not zero, and multiplying the whole by that element, changing the sign of this element, however, if it is removed by an odd number of elements from the principal diagonal. The principal diagonal is the line of elements beginning at the upper left-hand corner and ending at the lower right-hand corner. Thus,

$$\begin{vmatrix} 1 & 2 & 8 & 5 \\ 3 & 4 & 6 & 9 \\ 0 & 3 & 0 & 0 \\ 6 & 7 & 4 & 3 \end{vmatrix} = -3 \begin{vmatrix} 1 & 8 & 5 \\ 3 & 6 & 9 \\ 6 & 4 & 3 \end{vmatrix}$$

the principal diagonal being that with the figures 1, 4, 0, and 3. It is immaterial whether the distance from the diagonal is counted along a row or a column.

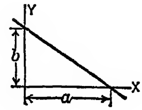
(5) The value of a determinant of the second order is

$$\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} = a_1 b_2 - a_2 b_1$$

The reduction of determinants is effected by altering the terms according to the above rules until a row or column is obtained in which all terms but one are zero. This enables a reduction of order to be effected in accordance with rule 4. Reductions are continued until one of the second order is obtained.

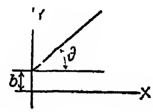
EQUATIONS OF COMMON CURVES. **Straight Line.**

$$\frac{x}{a}+\frac{y}{b}=1$$



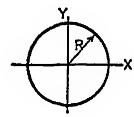
or

$$y = x \tan \theta + b.$$



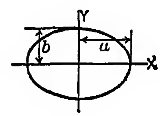
Circle.

$$x^2 + y^2 = R^2$$



Ellipse

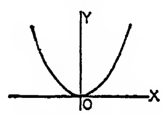
$$\frac{x^2}{a^2}+\frac{y^2}{b^2}=1.$$



Parabola (Vertical).

$$y = kx^2$$

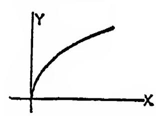
where k is a constant.



Parabola (Horizontal).

$$y = k\sqrt{x}$$

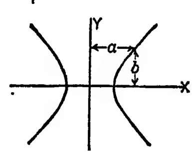
where k is a constant.



Hyperbola.

$$\frac{x^2}{a^2}-\frac{y^2}{b^2}=1 \text{ (Horizontal)}$$

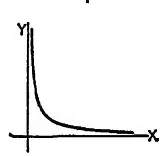
$$\frac{x^2}{a^2}-\frac{y^2}{b^2}=-1 \text{ (Vertical)}$$



Rectangular or Equilateral Hyperbola.

$$y = \frac{k}{x}$$

where k is a constant.



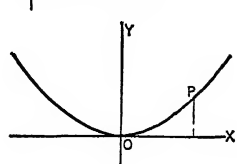
Catenary.

$$y = \frac{1}{k}\cosh kx - 1$$

where k is a constant. The length of arc from O to P is

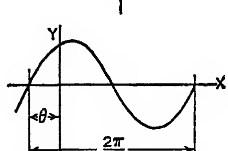
$$= \frac{1}{k}\sinh (kx)$$

See tables of hyperbolic functions.



Sinusoid.

$$y = A \sin (ax + \theta).$$



2. COMPLEX QUANTITIES

The square root of a negative quantity is called an "imaginary" quantity, or a pure imaginary. A quantity consisting of the sum or difference of a real quantity and an imaginary quantity is called a "complex" quantity. All the rules of ordinary algebra apply to pure imaginaries and complex quantities. The square root of minus one is called the imaginary unit and is usually represented by the symbol j (writers on pure mathematics use the symbol i), that is,

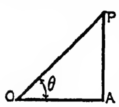
$$j = \sqrt{-1}$$

Any complex quantity may then be written

$$a + jb$$

where a and b are both real quantities.

GEOMETRICAL REPRESENTATION OF A COMPLEX QUANTITY. A positive real quantity may be represented by a line drawn on a plane in a given direction; a negative real quantity may be represented by a line drawn in the opposite direction. Multiplying a quantity by -1 then reverses its direction. Also, since multiplying a real quantity by $\sqrt{-1}$ twice is equivalent to multiplying it by -1, the operation of multiplying once by $\sqrt{-1}$ may be represented by turning the line representing the quantity through 90° in the positive direction of rotation. The positive direction of rotation is taken as the opposite direction to that in which the hands of a clock move. Hence, a complex quantity $a + jb$ may be represented by the line OP in the figure, where $OA = a$ and $AP = b$. The complex quantity $a + jb$ is then completely specified by a line of length $\sqrt{a^2 + b^2}$ making an angle θ, with the axis of reference OX where $\tan\theta = \frac{b}{a}$. The length $M = \sqrt{a^2 + b^2}$ is called the magnitude of the complex quantity, and the angle $\theta = \tan^{-1}\frac{b}{a}$ is called its angle. From the figure it is evident that the complex quantity $a + jb$ may also be written



$$a + jb = M(\cos\theta + j\sin\theta)$$

Expanding $\cos\theta$ and $\sin\theta$ into series (see Series) and adding, the resultant series obtained is the series for $e^{j\theta}$; hence

$$a + jb = Me^{j\theta} \qquad (1)$$

From the above definitions and equation (1) it is evident that complex numbers possess the following properties:

ADDITION OF TWO COMPLEX QUANTITIES.

$$(a + jb) + (a_1 + jb_1) = (a + a_1) + j(b + b_1)$$

SUBTRACTION OF TWO COMPLEX QUANTITIES.

$$(a + jb) - (a_1 + jb_1) = (a - a_1) + j(b - b_1)$$

MULTIPLICATION OF A COMPLEX QUANTITY BY A COMPLEX NUMBER.

$$(a + jb)(a_1 + jb_1) = aa_1 - bb_1 + j(ab_1 + a_1 b)$$

or, putting $\quad a + jb = Me^{j\theta}$ and $a_1 + jb_1 = M_1 e^{j\theta_1}$

where $\quad M = \sqrt{a^2 + b^2}, \quad M_1 = \sqrt{a_1^2 + b_1^2}$

$$\tan\theta = \frac{b}{a}$$

and

$$\tan\theta_1 = \frac{b_1}{a_1}$$

we have $\quad (a + jb)(a_1 + jb_1) = Me^{j\theta} M_1 e^{j\theta_1} = MM_1 e^{j(\theta + \theta_1)}$

Hence the product of two complex quantities is in general a complex quantity which has a magnitude equal to the product of the magnitudes of the two quantities and an angle equal to the sum of the angles of the two quantities.

DIVISION OF A COMPLEX QUANTITY BY A COMPLEX NUMBER.

$$\frac{a + jb}{a_1 + jb_1} = \frac{(a + jb)(a_1 - jb_1)}{(a_1 + jb_1)(a_1 - jb_1)} = \frac{aa_1 + bb_1 - j(ab_1 - a_1 b)}{a_1^2 + b_1^2}$$

or

$$\frac{a + jb}{a_1 + jb_1} = \frac{Me^{j\theta}}{M_1 e^{j\theta_1}} = \frac{M}{M_1} e^{j(\theta - \theta_1)}$$

Hence the quotient of two complex quantities is in general a complex quantity which has a magnitude equal to the quotient of the magnitudes of the two quantities and an angle equal to the difference of the angles of the two quantities.

EQUATIONS CONTAINING COMPLEX QUANTITIES. Since a real quantity cannot be equal to an imaginary quantity it follows that any equation of the form

$$A + jB = A_1 + jB_1$$

where A, B, A_1, and B_1 are all real quantities (which may, however, consist of any number of terms), is equivalent to the two equations

$$A = A_1$$

and

$$B = B_1$$

Also, if one member of an equation reduces to the form $A + jB$, then the other member of this equation must likewise contain an equal real and an equal imaginary part.

3. TRIGONOMETRIC FORMULAS

The trigonometric functions of an angle are the ratios to one another of the various sides of a right triangle having the given angle as one of its angles. Referring to Fig. 1, let B, P and H be the three sides of a triangle. Then the trigonometric functions of the angle x are

sine of x, abbreviated $\sin x = \frac{P}{H}$; cotangent of x, abbreviated $\cot x = \frac{B}{P}$

cosine of x, abbreviated $\cos x = \frac{B}{H}$; secant of x, abbreviated $\sec x = \frac{H}{B}$

tangent of x, abbreviated $\tan x = \frac{P}{B}$; cosecant of x, abbreviated $\csc x = \frac{H}{P}$

When B, P and H are limited to the three sides of a right triangle, the above definitions are directly applicable only to angles lying between 0 and 90°. The definitions, however, may be extended by considering the point A (Fig. 2) as describing a circle of radius OA

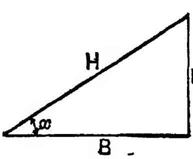


Fig. 1

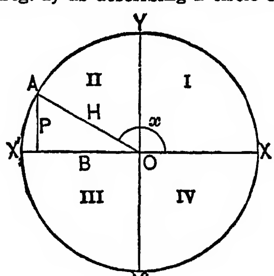

Fig. 2

with the center at O. Let XX' be the horizontal diameter and YY' the vertical diameter of this circle, and call P the perpendicular distance from A to the line XX' and B the horizontal distance from A to YY'. P is to be considered positive when A lies above XX', negative when below. B is considered positive when A is to the right of YY' and negative when to the left. The four quarters of the circle are called quadrants, and are designated as the first, second, third and fourth quadrants as indicated. The angle is said to lie in the quadrant in which the point A lies. In Fig. 2 the angle x is in the second quadrant.

Algebraic Signs of the Functions

	Sine	Cosine	Tangent
Angle in first quadrant......	+	+	+
Angle in second quadrant....	+	−	−
Angle in third quadrant.....	−	−	+
Angle in fourth quadrant....	-	+	−

Period. From the above definitions it is evident that adding 2π radians or 360° to an angle does not change the value of any of its functions, that is, these functions repeat themselves every time the angle increases by the 2π radians or 360°. They are therefore said to have a period equal to 2π radians or 360°.

Functions of Angles in Any Quadrant in Terms of Angles in First Quadrant.

$$\begin{aligned}
\sin(-x) &= -\sin x & \sin(90+x) &= \cos x\\
\cos(-x) &= \cos x & \cos(90+x) &= -\sin x\\
\tan(-x) &= -\tan x & \tan(90+x) &= -\cot x\\
\sin(180-x) &= \sin x & \sin(180+x) &= -\sin x\\
\cos(180-x) &= -\cos x & \cos(180+x) &= -\cos x\\
\tan(180-x) &= -\tan x & \tan(180+x) &= \tan x\\
\sin(270-x) &= -\cos x & \sin(270+x) &= -\cos x\\
\cos(270-x) &= -\sin x & \cos(270+x) &= \sin x\\
\tan(270-x) &= \cot x & \tan(270+x) &= -\cot x
\end{aligned}$$

Anti-functions. If $a = \sin x$, then x is the angle whose sine is a; this may be expressed symbolically $x = \sin^{-1} a$, which is read "x equals the angle whose sine is a." The angle x is also called the "anti-sine" or the "inverse sine" of a. Similar notation is used for the other functions; for example, $x = \cos^{-1} b$ is used to express the relation that x is the angle whose cosine is b. At least two "anti-functions" must be known to completely determine the quadrant in which an angle lies; for example, if $x = \sin^{-1} 0.5$ then x may be either 30° or 150°, but if we also have $x = \cos^{-1} 0.866$, then x must equal 30°, while if $x = \cos^{-1}(-0.866)$, then x must equal 150°.

Anti-functions may be taken from the Trigonometric Tables by finding the angle in the margin corresponding to the function in the table.

Example. $\sin^{-1} 0.319 = 18.6°$ or $180° - 18.6° = 161.4°$.

Versine. The expression $(1 - \cos x)$ is called the "versine" of x.

Relations Among Functions of the Same Angle.

$$\tan x = \frac{\sin x}{\cos x} = \frac{1}{\cot x} \qquad \sin^2 x + \cos^2 x = 1$$

$$\sec x = \frac{1}{\cos x} \qquad 1 + \tan^2 x = \frac{1}{\cos^2 x}$$

$$\csc x = \frac{1}{\sin x} \qquad 1 + \cot^2 x = \frac{1}{\sin^2 x}$$

$$\begin{aligned}
\sin(90-x) &= \cos x & \sin(-x) &= -\sin x\\
\cos(90-x) &= \sin x & \cos(-x) &= \cos x\\
\tan(90-x) &= \cot x & \tan(-x) &= -\tan x
\end{aligned}$$

Sum and Difference of Two Angles.

$$\sin(x+y) = \sin x \cos y + \cos x \sin y$$
$$\cos(x+y) = \cos x \cos y - \sin x \sin y$$
$$\tan(x+y) = \frac{\tan x + \tan y}{1 - \tan x \tan y}$$
$$\sin(x-y) = \sin x \cos y - \cos x \sin y$$
$$\cos(x-y) = \cos x \cos y + \sin x \sin y$$
$$\tan(x-y) = \frac{\tan x - \tan y}{1 + \tan x \tan y}$$

Product of the Functions of Two Angles.

$$\sin x \sin y = \tfrac{1}{2}[\cos(x-y) - \cos(x+y)]$$
$$\sin x \cos y = \tfrac{1}{2}[\sin(x+y) + \sin(x-y)]$$
$$\cos x \sin y = \tfrac{1}{2}[\sin(x+y) - \sin(x-y)]$$
$$\cos x \cos y = \tfrac{1}{2}[\cos(x+y) + \cos(x-y)]$$

Functions of Twice an Angle.

$$\sin 2x = 2 \sin x \cos x \qquad \cos 2x = \cos^2 x - \sin^2 x = 2\cos^2 x - 1$$

$$\tan 2x = \frac{2\tan x}{1 - \tan^2 x}$$

Functions of Half an Angle.

$$\sin\frac{x}{2} = \sqrt{\frac{1-\cos x}{2}} \qquad \cos\frac{x}{2} = \sqrt{\frac{1+\cos x}{2}} \qquad \tan\frac{x}{2} = \sqrt{\frac{1-\cos x}{1+\cos x}}$$

Functions of Three Times an Angle.

$$\sin 3x = 3\sin x - 4\sin^3 x \qquad \cos 3x = 4\cos^3 x - 3\cos x$$

$$\tan 3x = \frac{3\tan x - \tan^3 x}{1 - 3\tan^2 x}.$$

TRIGONOMETRY. Any triangle is completely defined when, (1) two sides and the included angle are known, (2) one side and two angles are known, (3) three sides are known. Let the sides and angles of a triangle be designated as in Fig. 1.

1. Given two sides a and b, and the included angle γ. Then

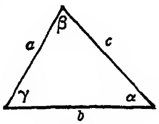

FIG. 3

$$c = \sqrt{a^2 + b^2 - 2\,ab\cos\gamma}$$

$$\sin\alpha = \frac{a}{c}\sin\gamma$$

$$\beta = 180 - \alpha - \gamma.$$

2. Given the side a and the two angles β and γ. Then

$$\alpha = 180 - \beta - \gamma$$

$$b = a\frac{\sin\beta}{\sin\alpha}$$

$$c = a\frac{\sin\gamma}{\sin\alpha}$$

3. Given the three sides a, b and c. Put

$$s = {}^1\!/_2\,(a + b + c)$$

Then

$$\sin\alpha = \frac{2}{bc}\sqrt{s(s-a)(s-b)(s-c)}$$

$$\sin\beta = \frac{b}{a}\sin\alpha$$

$$\gamma = 180 - \alpha - \beta$$

Relations Between Sides and Angles. The following relations between the sides and angles of a triangle are sometimes useful:

$$\frac{a}{\sin\alpha} = \frac{b}{\sin\beta} = \frac{c}{\sin\gamma}$$

$$\cos\alpha = \frac{b^2 + c^2 - a^2}{2\,bc}$$

$$\sin\frac{\alpha}{2} = \sqrt{\frac{(s-b)(s-c)}{bc}}$$

$$\cos\frac{\alpha}{2} = \sqrt{\frac{s(s-a)}{bc}}$$

and similar relations for the other two angles.

4. EXPONENTIAL AND HYPERBOLIC FORMULAS

When the relation between any variable y and another variable x is such that x occurs as an exponent of one or more terms, y is said to be an exponential function of x. Of particular importance in connection with electric circuits are the exponential functions e^x and e^{-x}, where e is the base of the natural logarithms. Since x is the natural logarithm of e^x, the value of e^x can be obtained from the table of common logarithms as shown at the beginning of that table. In addition the values of e^x and e^{-x} are given in a separate table.

Hyperbolic functions are an extension of the trigonometric functions to those cases where the use of the latter gives rise to imaginary or complex angles. From the relations,

$$\cos x = \frac{e^{jx} + e^{-jx}}{2}$$

$$\sin x = \frac{e^{jx} - e^{-jx}}{2j}$$

where $j = \sqrt{-1}$, it follows that, putting $x = jz$:

$$\cos jz = \frac{e^z + e^{-z}}{2} \tag{1}$$

$$-j\sin jz = \frac{e^z - e^{-z}}{2} \tag{2}$$

Expressions (1) and (2) are both real quantities when z is real, that is, when the angle jz is imaginary. The first expression is called the hyperbolic cosine of z, abbreviated and pronounced " cosh "; the second expression is called the hyperbolic sine of z, abbreviated sinh and pronounced " shin." Hence, using x for the variable.

$$\sinh x = \frac{e^x - e^{-x}}{2}$$

$$\cosh x = \frac{e^x + e^{-x}}{2}$$

The hyperbolic tangent, cotangent, secant, and cosecant are defined as follows:

$$\tanh x = \frac{\sinh x}{\cosh x}$$

$$\coth x = \frac{\cosh x}{\sinh x}$$

$$\operatorname{sech} x = \frac{1}{\cosh x}$$

$$\operatorname{csch} x = \frac{1}{\sinh x}$$

The hyperbolic angle x is a number analogous to radians in circular measure; it is never expressed in degrees.

Adding 2π to an angle does not change the value of the trigonometric functions; they are therefore said to have a period equal to 2π radians. Hyperbolic functions, however, have no true period, but adding $2\pi j$ to the hyperbolic angle does not change the values of the functions; hence these functions have an imaginary period, $2\pi j$.

For the value of the hyperbolic functions see Table of Exponential and Hyperbolic Functions.

Approximate Formulas. Note that for x less than 0.1,

$$\text{Sinh } x = x \text{ with an error of less than 0.2 per cent}$$

$$\cosh x = 1 + \frac{x^2}{2} \text{ with an error of less than 0.09 per cent}$$

For x greater than 6,

$$\sinh x = \cosh x = \frac{e^x}{2} = \frac{1}{2}\log_{10}^{-1}(0.43429x)$$

with an error of less than 0.01 per cent.

Anti-functions. If $a = \sinh x$, then x is the angle whose hyperbolic sine is a; this may be expressed symbolically

$$x = \sinh^{-1} a$$

which is read " x equals the angle whose hyperbolic sine is a." The angle x is also called the " anti-hyperbolic sine " or the " inverse hyperbolic sine " of a. Similarly for the other hyperbolic functions. The following relations exist between the anti-hyperbolic functions and the natural logarithms:

$$\sinh^{-1} x = \log\left(x + \sqrt{x^2 + 1}\right)$$

$$\cosh^{-1} x = \log\left(x + \sqrt{x^2 - 1}\right)$$

$$\tanh^{-1} x = \frac{1}{2}\log\left(\frac{1+x}{1-x}\right)$$

Relations among Functions of the Same Angle.

$$\cosh^2 x - \sinh^2 x = 1$$

$$1 - \tanh^2 x = \frac{1}{\cosh^2 x}$$

$$\coth^2 x - 1 = \frac{1}{\sinh^2 x}$$

$$\sinh(-x) = -\sinh x$$

$$\cosh(-x) = \cosh x$$

$$\tanh(-x) = -\tanh x$$

See also the definitions given above.

Sum and Difference of Two Angles.

$$\sinh(x+y) = \sinh x \cosh y + \cosh x \sinh y$$
$$\cosh(x+y) = \cosh x \cosh y + \sinh x \sinh y$$
$$\tanh(x+y) = \frac{\tanh x + \tanh y}{1 + \tanh x \tanh y}$$
$$\sinh(x-y) = \sinh x \cosh y - \cosh x \sinh y$$
$$\cosh(x-y) = \cosh x \cosh y - \sinh x \sinh y$$
$$\tanh(x-y) = \frac{\tanh x - \tanh y}{1 - \tanh x \tanh y}$$

Product of the Functions of Two Angles.

$$\sinh x \sinh y = {}^1/_2[\cosh(x+y) - \cosh(x-y)]$$
$$\sinh x \cosh y = {}^1/_2[\sinh(x+y) + \sinh(x-y)]$$
$$\cosh x \sinh y = {}^1/_2[\sinh(x+y) - \sinh(x-y)]$$
$$\cosh x \cosh y = {}^1/_2[\cosh(x+y) + \cosh(x-y)]$$

Functions of Twice an Angle.

$$\sinh 2x = 2 \sinh x \cosh x$$
$$\cosh 2x = \sinh^2 x + \cosh^2 x = 2 \sinh^2 x + 1 = 2 \cosh^2 x - 1$$
$$\tanh 2x = \frac{2 \tanh x}{1 + \tanh^2 x}$$

Functions of Half an Angle.

$$\sinh \frac{x}{2} = \sqrt{\frac{\cosh x - 1}{2}}$$
$$\cosh \frac{x}{2} = \sqrt{\frac{\cosh x + 1}{2}}$$
$$\tanh \frac{x}{2} = \sqrt{\frac{\cosh x - 1}{\cosh x + 1}}$$

Functions of Three Times an Angle.

$$\sinh 3x = 3 \sinh x + 4 \sinh^3 x$$
$$\cosh 3x = 4 \cosh^3 x - 3 \cosh x$$
$$\tanh 3x = \frac{3 \tanh x + \tanh^3 x}{1 + 3 \tanh^2 x}$$

Relations between Hyperbolic and Trigonometric Functions.

$$\sinh(jx) = j \sin x \qquad \sin(jx) = j \sinh x$$
$$\cosh(jx) = \cos x \qquad \cos(jx) = \cosh x$$
$$\tanh(jx) = j \tan x \qquad \tan(jx) = j \tanh x$$
$$\sinh^{-1} jx = j \sin^{-1} x \qquad \sin^{-1} jx = j \sinh^{-1} x$$
$$\tanh^{-1} jx = j \tan^{-1} x \qquad \tan^{-1} jx = j \tanh^{-1} x$$
$$\cosh^{-1} jx = j \cos^{-1} jx = \log(x + \sqrt{1+x^2}) - j\frac{\pi}{2}$$

Hyperbolic Functions of a Complex Angle.

$$\sinh(x+jy) = \sinh x \cos y + j \cosh x \sin y = Me^{j\theta}$$

where $M = \sqrt{\dfrac{\cosh 2x - \cos 2y}{2}}$ and $\tan \theta = \dfrac{\tan y}{\tanh x}$

$$\cosh(x+jy) = \cosh x \cos y + j \sinh x \sin y = Ne^{j\phi}$$

where $N = \sqrt{\dfrac{\cosh 2x + \cos 2y}{2}}$ and $\tan \phi = \tanh x \cdot \tan y$

$$\tanh(x+jy) = \frac{\sinh x \cos y + j \cosh x \sin y}{\cosh x \cos y + j \sinh x \sin y} = Pe^{j\psi}$$

where $P = \sqrt{\dfrac{\cosh 2x - \cos 2y}{\cosh 2x + \cos 2y}}$ and $\psi = \tan^{-1}\left[\dfrac{\sin 2y}{\sinh 2x}\right]$

$$\tanh^{-1}(Ae^{j\alpha}) = B_1 + jB_2$$

where $B_1 = \dfrac{1}{2}\tanh^{-1}\left[\dfrac{2A \cos \alpha}{1 + A^2}\right]$ and $B_2 = \dfrac{1}{2}\tan^{-1}\left[\dfrac{2A \sin \alpha}{1 - A^2}\right]$

5. CALCULUS FORMULAS

The formula for the integration by parts is:

$$\int_a^b u\,dv = [uv]_a^b - \int_a^b v\,du$$

The following table is used in the formulas

$$\frac{df(x)}{dx} = f'(x)$$

$$\int f'(x)dx = f(x) + C$$

where C is an arbitrary constant.

$f'(x)$	$f(x)$	$f'(x)$	$f(x)$
x^m	$\frac{1}{m+1}x^{m+1}$	$\frac{1}{\cos^2 ax}$	$\frac{1}{a}\tan ax$
$\frac{1}{ax}$	$\frac{1}{a}\log_e x$	$\frac{1}{\sin^2 ax}$	$-\frac{1}{a}\cot ax$
e^{ax}	$\frac{1}{a}e^{ax}$	$\frac{1}{\sqrt{a^2+bx^2}}$	$\frac{1}{\sqrt{-b}}\sin^{-1}\sqrt{-b}\,\frac{x}{a}$
a^{bx}	$\frac{1}{b\log a}a^{bx}$	$\frac{1}{x\sqrt{x^2+a}}$	$\frac{1}{\sqrt{-a}}\cos^{-1}\sqrt{-a}\,\frac{1}{x}$
$\cos ax$	$\frac{1}{a}\sin ax$	$\frac{x}{\sqrt{a^2\pm x^2}}$	$\pm\sqrt{a^2\pm x^2}$
$\sin ax$	$-\frac{1}{a}\cos ax$	$\frac{x}{\sqrt{x^2-a^2}}$	$\sqrt{x^2-a^2}$
$\cosh ax$	$\frac{1}{a}\sinh ax$	$\frac{u\frac{dv}{dx}-v\frac{du}{dx}}{u^2}$	$\frac{v}{u}$
$\sinh ax$	$\frac{1}{a}\cosh ax$	$\log x$	$x\log x - x$
$\tan ax$	$-\frac{1}{a}\log(\cos ax)$	$\sin^2 x$	$-\frac{1}{2}(\cos x\sin x - x)$
$\tanh ax$	$\frac{1}{a}\log(\cosh ax)$	$\cos^2 x$	$\frac{1}{2}(\sin x\cos x + x)$

MAXIMA AND MINIMA. Let y be any function of a variable x, then y will be a maximum or minimum for any value of x which satisfies

$$\frac{dy}{dx} = 0 \qquad (1)$$

provided $\frac{d^2y}{dx^2}$ is not zero. If the second derivative $\frac{d^2y}{dx^2}$ is positive for this value of x, then the corresponding value of y is a minimum; if this second derivative is negative, the corresponding value of y is a maximum.

In case $\frac{d^2y}{dx^2}$ is also zero for the value of x which satisfies (1), the corresponding value of y is not a maximum or minimum unless $\frac{d^3y}{dx^3}$ is also zero and $\frac{d^4y}{dx^4}$ is not zero. When $\frac{d^3y}{dx^3} = 0$, y is a minimum if $\frac{d^4y}{dx^4}$ is positive and a maximum if $\frac{d^4y}{dx^4}$ is negative. In case $\frac{d^4y}{dx^4}$ is also zero, similar relations must hold for the fifth and sixth derivatives, etc.

6. DIFFERENTIAL EQUATIONS

Differential equations of the following forms are met with in the theory of alternating and transient currents.

The following notation is used: $e = 2.7183 \ldots =$ base of natural system of logarithms; x, y, z are variables. A, ϕ, γ, and θ are constants of integration or arbitrary constants. Other letters represent known constants.

$$\frac{dy}{dx} = ay \tag{1}$$

Solution:

$$y = Ae^{ax}$$

$$\frac{dy}{dx} + ay = 0 \tag{2}$$

Solution:

$$y = Ae^{-ax}$$

$$\frac{dy}{dx} + ay = b \tag{3}$$

Solution:

$$y = \frac{b}{a}[1 - Ae^{-ax}]$$

$$\frac{d^2 y}{dx^2} = - a^2 y \tag{4}$$

Solution:

$$y = A \sin (ax + \phi)$$

$$\frac{d^2 y}{dx^2} = a^2 y \tag{5}$$

Solution:

$$y = A \sinh (ax + \phi)$$

$$\frac{d^2 y}{dx^2} + 2u\frac{dy}{dx} + (u^2 + a^2)y = 0 \tag{6}$$

Solution:

Case I. a^2 positive: $y = Ae^{-ux} \sin (ax + \phi)$
Case II. a^2 negative: $y = Ae^{-ux} \sinh (ax + \phi)$
Case III. $a^2 = 0$: $y = A(x + \phi)e^{-ux}$

$$\frac{d^2 y}{dx^2} + 2u\frac{dy}{dx} + (u^2 + a^2)y = B \sin (\omega x + \theta) \tag{7}$$

The complete solution of this equation consists of the solution of (6) plus the term

$$\left(\frac{B \sin \delta}{2u\omega}\right) \sin (\omega x + \theta - \delta) \tag{a}$$

where

$$\delta = \tan^{-1} \frac{2u\omega}{a^2 + u^2 - \omega^2}$$

For each additional sine term added to the right-hand member of the equation, there will be a corresponding term of the same form as (*a*) in the solution.

$$\frac{d^n y}{dx^n} + a_{n-1}\frac{d^{n-1} y}{dx^{n-1}} + \ldots a_1\frac{dy}{dx} + a_0 y = B \sin (\omega x + \theta) \tag{8}$$

Solution:

$$y = A_1 e^{m_1 x} + A_2 e^{m_2 x} + \ldots A_n e^{m_n x} + KB \sin (\omega X + \theta + \delta)$$

where m_1, m_2, etc., are the n roots of the equation

$$m^n + a_{n-1} m^{n-1} + \ldots a_1 m + a_0 = 0,$$

and K and δ are found by substituting the $KB \sin (\omega x + \theta + \delta)$ by itself in the given differential equation and equating the coefficients of $\sin (\omega x + \theta)$ and $\cos (\omega x + \theta)$ respectively on the two sides of the resulting equation. When the second member of the differential equation is a constant, B, the sine term in the solution becomes simply $\frac{B}{a_0}$.

Note that all the preceding equations are merely special cases of the general equation (8).

$$\frac{d^2 y}{dx^2} + 2u\frac{dy}{dx} + (u^2 - q^2)y = \frac{1}{c^2}\frac{d^2 y}{dz^2} \tag{9}$$

The complete solution of this equation contains an infinite number of terms of the form

$$y = e^{-(u-s)x}\,[A_1\, e^{mz} \sin(\omega x + nz + \phi_1) + A_2\, e^{-mz} \sin(\omega x - nz + \phi_2)] \qquad (a)$$

where A_1, ϕ_1, A_2, ϕ_2 and two of the four constants ω, s, m, and n are integration constants (fixed by the terminal conditions). The values of m and n in terms of ω and s are

$$m = c\sqrt{ab}\cos\frac{\eta + e}{2}$$

$$n = c\sqrt{ab}\sin\frac{\eta + e}{2}$$

where $a = \sqrt{(s+q)^2 + \omega^2}$, $\qquad e = \tan^{-1}\left(\frac{\omega}{s+q}\right)$

$b = \sqrt{(s-q)^2 + \omega^2}$, $\qquad \eta = \tan^{-1}\left(\frac{\omega}{s-q}\right)$

The values of ω and s in terms of m and n are

$$\omega = \frac{\sqrt{FG}}{c}\cos\frac{\alpha + \beta}{2}$$

$$s = \frac{\sqrt{FG}}{c}\sin\frac{\alpha + \beta}{2}$$

where $F = \sqrt{(n + cq)^2 + m^2}$, $\qquad \alpha = \tan^{-1}\left(\frac{m}{n + cq}\right)$

$G = \sqrt{(n - cq)^2 + m^2}$, $\qquad \beta = \tan^{-1}\left(\frac{m}{n - cq}\right)$

The solution of equation (9) may also be written as a series of terms of the form

$$y = Me^{-(u-s)x}\sin(\omega x + \phi + \mu) \qquad (b)$$

where

$$M = \frac{A}{\sqrt{2}}\sqrt{\cosh 2(mz + \gamma) + \cos 2(nz + \theta)}$$

$$\tan\mu = \tanh(mz + \gamma)\tan(nz + \theta)$$

where A, ϕ, γ, and θ are integration constants, and the relations between the other constants ω, s, m, and n are the same as above.

In the special case when $q = 0$, the solution of equation (9) is

$$y = e^{-ux}\,[f_1(\omega x + nz) + f_2(\omega x - nz)] \qquad (c)$$

where f_1 and f_2 are any two arbitrary functions and ω and n are connected by the relation

$$\frac{\omega}{n} = \frac{1}{c}$$

$$\frac{d^2 y}{dx^2} + \frac{1}{x}\frac{dy}{dx} = -4a^2 y \qquad (10)$$

This is known as Bessel's equation of zero order. One solution is the infinite series:

$$y = A\left[1 - (ax)^2 + \frac{(ax)^4}{(2!)^2} - \frac{(ax)^6}{(3!)^2} + \frac{(ax)^8}{(4!)^2} - \cdots\right] \qquad (a)$$

If $A = 1$, y is Bessel's function of the first kind of zero order. This series is absolutely convergent for all values of x, but for $ax > 1$ the following asymptotic series is more convenient and sufficiently accurate.

$$y = \frac{Be^{2ax}}{\sqrt{2ax}}\left[1 + \frac{1}{16ax} + \frac{3^2}{2!(16ax)^2} + \frac{3^2\cdot 5^2}{3!(16ax)^3} + \frac{3^2\cdot 5^2\cdot 7^2}{4!(16ax)^4}\right] \qquad (b)$$

---

7. ERRORS OF OBSERVATION

When a quantity is measured with all possible accuracy many times in succession, the numbers expressing the results are found to differ by amounts which, although generally small, are occasionally considerable in comparison with the quantity measured. Though these differences may be decreased by improved methods, better instruments, or greater skill, they can never be entirely removed. They are known as the errors of observation. The following formulas, which are derived from the theory of least squares, apply to such errors and not to errors which can be eliminated by correcting mistakes of the observer or defects of instruments or methods of observation. That is, they apply only to errors

which may be either positive or negative, the chance of a positive error occurring being exactly the same as the chance of a negative error occurring.

WEIGHTED OBSERVATIONS. Sometimes, in spite of the care with which observations are taken, there are reasons for believing that some observations are better than others. In this case the observations are given different "weights" or numbers expressing their relative practical worth. A weighted observation is an observation multiplied by its weight.

PROBABLE VALUE OF SEVERAL OBSERVATIONS. The most probable value of a quantity which is observed directly several times with equal care is the arithmetical mean of the measurements.

The most probable value of a quantity which is observed directly several times, but the observations of which have different weights, is equal to the sum of the weighted observations divided by the sum of the weights.

PROBABLE ERROR OF ANY ONE OF SEVERAL OBSERVATIONS. The probable error or dispersion of a number of direct observations made with equal care is given by the following formula:

$$r = 0.6745\sqrt{\frac{\Sigma v^2}{n-1}}$$

where n = number of observations.
r = probable error of a single observation.
v = residual found by subtracting the arithmetical mean from each measurement.

The probable error of each of a number of direct observations, where the observations have different weight, is found by the following formula, in which p represents the weight of an observation.

$$r_1 = 0.6745\sqrt{\frac{\Sigma pv^2}{n-1}}$$

PROBABLE ERROR OF THE ARITHMETICAL MEAN. If

r = probable error of a single observation
n = number of observations,
r_0 = probable error of the arithmetical mean,

$$r_0 = \frac{r}{\sqrt{n}} \text{ for observations of equal weight}$$

or

$$r_0 = \frac{r_1}{\sqrt{\Sigma p}} \text{ for unequal weight}$$

It should be noted that the probable error of the mean decreases inversely as the square root of the number of observations.

PROBABLE ERROR IN A RESULT CALCULATED FROM THE MEANS OF SEVERAL OBSERVED QUANTITIES. Let Z = a sum or difference of several independent quantities.

Let r_1, r_2, r_3, etc., be the probable errors in these quantities. Then the probable error of Z is equal to

$$\sqrt{r_1^2 + r_2^2 + r_3^2 + \text{etc.}}$$

Let $Z = Az$, where z is an observed quantity, and A, a known number. Let r be the probable error in z. Then the probable error in Z is Ar.

Let Z be the product of two independently observed quantities z_1 and z_2 whose probable errors are r_1 and r_2 respectively. Then the error in Z is equal to

$$\sqrt{z_1^2 r_2^2 + z_2^2 r_1^2}$$

Let Z be any function of the independently observed quantities z_1, z_2, z_3, etc., whose probable errors are r_1, r_2, r_3, etc. Then the probable error in Z is equal to

$$\sqrt{\left(\frac{\partial Z}{\partial z_1}\right)^2 r_1^2 + \left(\frac{\partial Z}{\partial z_2}\right)^2 r_2^2 + \left(\frac{\partial Z}{\partial z_3}\right)^3 r_3^2 + \text{etc.}}$$

8. APPROXIMATIONS

If a is small

$$(1 \pm a)^m = 1 \pm ma$$

If m is nearly equal to n

$$\sqrt{mn} = \frac{m+n}{2}$$

If θ is small compared to a radian

$$\sin\theta = \tan\theta = \theta \text{ radians}$$

9. SERIES

Taylor's series is written

$$f(x+h) = f(x) + \frac{h}{1!}f'(x) + \frac{h^2}{2!}f''(x) + \dots$$
$$= f(h) + \frac{x}{1!}f'(h) + \frac{x^2}{2!}f''(h) + \dots$$

where the prime on the function means the derivative with respect to the argument

The following series are frequently useful.

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \dots$$
$$a^x = 1 + x\log a + \frac{(x\log a)^2}{2!} + \frac{(x\log a)^3}{3!} + \dots$$
$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots$$
$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots$$
$$\cos(x\sin\theta) = J_0(x) + 2\{J_2(x)\cos 2\theta + J_4(x)\cos 4\theta + \dots$$

where $J_n(x)$ is Bessel's function of order n,

$$\sin(x\sin\theta) = 2\{J_1(x)\sin\theta + J_3(x)\sin 3\theta + \dots$$

10. MENSURATION

The term mensuration is used in this article to include the relations between the areas and volumes of geometric figures and their linear dimensions.

Triangle.

$$\text{Area} = {}^1/_2\,(\text{Base}) \times (\text{Perpendicular height})$$
$$= \sqrt{s(s-a)(s-b)(s-c)}$$

where a, b, and c are the lengths of the three sides respectively, and $s = {}^1/_2\,(a+b+c)$

Trapezoid.

$$\text{Area} = \left(\frac{a+b}{2}\right)d$$

where a and b are the lengths of the parallel sides respectively, and d their distance apart.

Parallelogram.

$$\text{Area} = (\text{Base}) \times (\text{Perpendicular height})$$

Parabola.

$$\text{Area} = {}^2/_3\,(\text{Area of circumscribing triangle})$$

Cycloid.

$$\text{Area} = {}^3/_4\,\pi x\,(\text{Altitude})^2$$

the altitude being the diameter of the rolling circle.

Circle.

$$\text{Circumference} = 2\pi r = \pi d$$
$$\text{Area} = \pi r^2 = \frac{\pi}{4}d^2$$

where r is the radius and d the diameter.

$$\text{Area of segment} = \frac{r^2}{2}(\theta - \sin\theta)$$

where θ is the angle in radians (see Angles) subtended by the arc of the segment. If n is the height of the segment, measured along the radius perpendicular to the chord,

$$\text{Area of segment} = \pi r^2 M - A(r-n)$$

where $$A = \sqrt{n(2r-n)} \quad \text{and} \quad M = \frac{1}{180}\sin^{-1}\left(\frac{A}{r}\right)$$

Ellipse.

$$\text{Area} = \pi ab$$

where a and b are the principal semi-axes.

Prism with Parallel Sides and Parallel Ends.

$$\text{Volume} = (\text{Area of end}) \times (\text{Perpendicular distance between ends})$$

Right Circular Cylinder.

$$\text{Volume} = \frac{\pi}{4} d^2 l$$

where d is the diameter and l the length.

$$\text{Total surface of right cylinder} = \pi d(l + {}^1\!/_2 d)$$

Right Circular Cone.

$$\text{Volume} = {}^1\!/_3 \text{ (Area of base)} \times \text{(Height)}$$
$$= {}^1\!/_3 \text{ (Volume of circumscribing cylinder)}$$

where r is the radius of base and h the height of the cone.

$$\text{Area of curved surface of a right circular cone} = \pi r \sqrt{h^2 + r^2}$$

Right Pyramid.

$$\text{Volume} = {}^1\!/_3 \text{ (Area of base)} \times \text{(Height)},$$
$$\text{Volume of frustum of pyramid} = {}^1\!/_3 \text{ (Height)} (A + \sqrt{aA})$$

where A and a are the areas of the ends respectively.

Sphere.

$$r = \text{radius}$$
$$\text{Area of surface} = 4\pi r^2 = {}^2\!/_3 \text{ (total area of circumscribing cylinder)}$$

Area of the surface of a zone of a sphere = area of zone of the same height as this zone projected on to a cylinder.

$$\text{Volume} = {}^4\!/_3 \pi r^3 = {}^2\!/_3 \text{ (volume of circumscribing cylinder)}$$

Volume of a frustum of a sphere $= \pi r^2 (k \pm h) - \frac{\pi}{3} (k^3 \pm h^3)$, where k is the distance of its outer face from center and h the distance of its inner face from the center, the negative signs in the brackets to be used if both faces are on the same side of the center and the positive signs if on opposite sides of the center.

Ellipsoid.

$$\text{Volume} = {}^4\!/_3 \pi abc$$

where a, b, and c are the three principal semi-axes, respectively.

Paraboloid. Volume of a paraboloid of revolution equals one-half that of the circumscribing cylinder.

MATHEMATICAL TABLES

11. COMMON AND NATURAL LOGARITHMS OF NUMBERS

The common logarithm of a number is the index of the power to which the base 10 must be raised in order to equal the number.

The common logarithm of every positive number not an integral power of 10 consists of an *integral* and a *decimal part*. The integral part or whole number is called the *characteristic* and may be either *positive or negative*. The decimal or fractional part is a *positive* number called the *mantissa* and is the same for all numbers which have the same sequential digits.

The characteristic of the logarithm of any positive number greater than one is positive and is one less than the number of digits before the decimal point.

The characteristic of the logarithm of any positive number less than one is negative and is one more than the number of ciphers immediately after the decimal point.

A negative number or number less than zero has no real logarithm.

EXAMPLES: $\text{Log}_{10}\ 25400. = 4.404834$ $\text{Log}_{10}\ 0.0254 = \bar{2}.404834$ or $8.404834 - 10$

The two systems of logarithms in general use are the common or Briggsian logarithms, introduced in 1615 by Henry Briggs, a contemporary of John Napier, the inventor of logarithms, and the natural or less appropriately termed Napierian or hyperbolic logarithms, which developed somewhat accidentally from Napier's original work. The latter have a base denoted by e, an irrational number, which is:

$$e = \text{Lim}_{u=\infty}\left(1 + \frac{1}{u}\right)^u = 1 + 1 + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \ldots = 2.7182818$$

To obtain the natural logarithm, the common logarithm given below is multiplied by $\log_e 10$ which is 2.302585, or $\log_e N = 2.302585 \log_{10} N$.

12. TRIGONOMETRIC TABLES

The following tables give the values of sin x, cos x, and tan x for values of x from 0 to 90° in intervals of 0.1 degree. By making use of the periodic character of these functions, the values can be determined from these tables for all values of x to an accuracy of 0.1 degree. (See Trigonometric Formulas.)

If the angle is given in radians multiply the number of radians by $\frac{180}{\pi}$ (57.295) to obtain the number of degrees.

Trigonometric Functions **0.0°–15.9°**

13. EXPONENTIAL AND HYPERBOLIC TABLES

The following tables give values of e^x, e^{-x}, $\sinh x$, $\cosh x$ and $\tanh x$ for values of x from 0.00 to 6.00 in intervals of 0.01.

To facilitate computations involving multiplication, the common logarithms of e^x, $\sinh x$, $\cosh x$, and $\tanh x$ are also given.

For values of x greater than 6, e^x may be computed from the relationship $e^x = \log^{-1} (x \log_{10} e) = \log^{-1} 0.43429x$; e^{-x} approaches zero; $\sinh x$ and $\cosh x$ are approximately equal and become $0.5\, e^x$; and $\tanh x$ and $\coth x$ have values approximately equal to unity.

Where more accurate values of the exponentials and functions are required they may be computed from the following relationships.

$$e = 2.71828\ 18285 \qquad \frac{1}{e} = 0.36787\ 94412$$

$$M = \log_{10} e = 0.43429\ 44819 \qquad \frac{1}{M} = \log_e 10 = 2.30258\ 50930$$

$$e^x = \log^{-1} Mx \qquad e^{-x} = \log^{-1} - Mx$$

$$\sinh x = \frac{e^x - e^{-x}}{2} \qquad \cosh x = \frac{e^x + e^{-x}}{2} \qquad \tanh x = \frac{e^x - e^{-x}}{e^x + e^{-x}}$$

$$\operatorname{csch} x = \frac{1}{\sinh x} \qquad \operatorname{sech} x = \frac{1}{\cosh x} \qquad \coth x = \frac{1}{\tanh x}$$

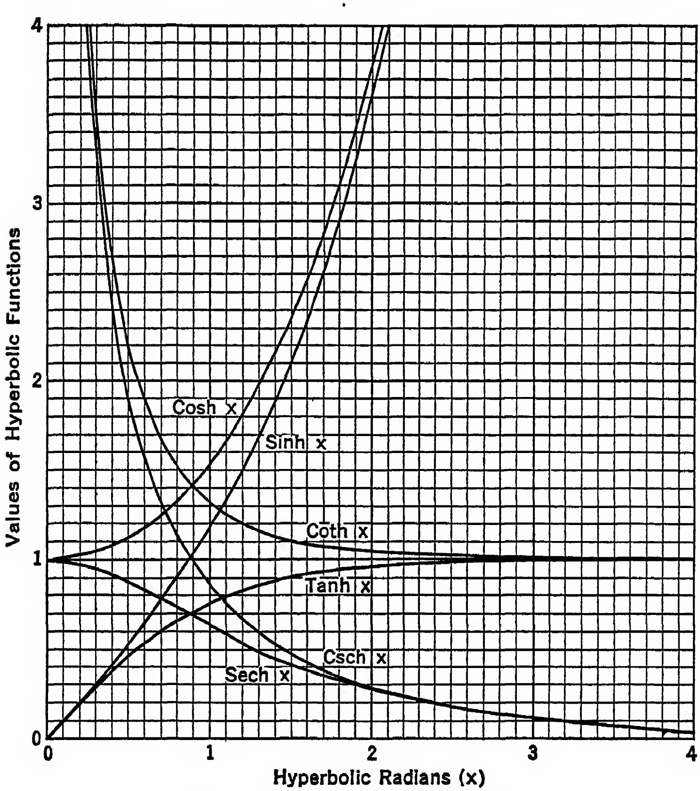

Chart of the Hyperbolic Functions.

UNITS AND CONVERSION FACTORS

By J. G. Brainerd and Carl C. Chambers

14. SYSTEMS OF UNITS

The magnitude of a physical quantity has no tangible meaning except as the relative magnitude of that quantity as compared with some other quantity of the same nature. Thus, 50 ohms is a resistance having a magnitude 50 times the resistance of 1 ohm. Therefore, whenever it is necessary or desirable to talk about the magnitude of a physical quantity, it is necessary to have a basis for comparison. This basis for a quantity is called the *unit* of magnitude of that quantity. In order to communicate the idea of magnitude between different people, it is necessary that they at least know the relative magnitudes of their units. It is the purpose of this section to act as tool for the specification of the relative magnitudes of the more commonly used systems of units for physical quantities.

Because of the relations defining physical laws, there are relations between the magnitudes of physical quantities. It is desirable that these physical relations be expressed alike in the different systems of units. For instance, the relation mass $\times$ acceleration = force should be independent of the system of units. Therefore, unit mass times unit acceleration should equal unit force. This gives a relation among these three units.

Because of such physical relations, all the mechanical units can be derived from the units for three fundamental quantities. The three quantities ordinarily taken as fundamental are mass, length, and time. Thermal quantities are conveniently derived from these three quantities together with another fundamental quantity, temperature. Photometric quantities are derived from the three fundamental mechanical quantities together with luminous intensity as a fourth fundamental quantity.

Similarly, electrical and magnetic quantities are derived from the three fundamental mechanical quantities and one fundamental electrical or magnetic quantity.

Two systems of mechanical units are in use in English-speaking countries, the English and the metric systems. The metric system is used universally by physicists and to a great extent by engineers, although the English system is still very common in engineering. The English system uses the foot, the pound, and the second as the units for length, mass, and time, respectively. The metric system (as used in the current literature—see MKS system below) employs the meter, the kilogram, and the second as the units for length, mass, and time, respectively.

STANDARDS OF THE FUNDAMENTAL UNITS. The physical units upon which these fundamental units are based and the legalized standards of the United States and Great Britain are described below.

Standard of Length. The standard meter (100 cm) is the distance between two lines on a platinum-iridium bar carefully preserved at the Bureau of Weights and Measures, at Sèvres, France, when the bar is kept at a uniform temperature of 0 deg cent throughout. In the United States the yard (3 ft) was defined by Act of Congress, July 28, 1866, as

$$1 \text{ U. S. yard} = \frac{3600}{3937} \text{ meter}$$

and similarly the British imperial yard is defined by law as

$$1 \text{ British imperial yard} = \frac{3600}{3937.079} \text{ meter}$$

For engineering purposes the U. S. and British yards may be considered as identical.

Standard of Mass and Force. The standard kilogram (1000 grams) as a unit of mass is a cylinder of platinum preserved at the Bureau of Weights and Measures, at Sèvres, France. The U. S. pound avoirdupois is defined by law (Act of Congress, 1866) as $\frac{1}{2.2046}$ kg, but in 1893, the Superintendent of Weights and Measures, with the approval of the Secretary of the Treasury, declared the pound to be

$$1 \text{ U. S. lb} = \frac{1}{2.204622} \text{ kg}$$

The British imperial pound has the same value.

The same relations between the pound and kilogram hold whether these units be taken as units of mass or as units of force, the unit of force being defined in both cases as the pull of the earth on unit mass at 45 deg latitude and sea level.

Standard of Time. The standard second universally adopted is the $\frac{1}{86,400}$ part of a mean solar day. The solar day is the interval of time between two successive transits of the sun across a meridian of the earth at the point of observation: this interval varies in length at different times during the year, but the average length of the interval for one year is constant as far as can be determined by any known methods of observation.

Standard of Temperature. Two units of temperature, or temperature scales, are commonly employed, viz., the centigrade and the fahrenheit units. The relation between these two units results solely from the manner in which they are defined. One degree centigrade = $^9/_5$ fahr. Owing to the difference in the zeros of the two scales, a temperature of t_f degrees fahrenheit corresponds to a temperature of $t_c = {}^5/_9\,(t_f - 32)$ degrees centigrade, and vice versa, $t_f = {}^9/_5\, t_c + 32$ degrees fahrenheit.

Standard of Luminous Intensity. The standard of luminous intensity is the mean intensity in the horizontal plane from a group of incandescent lamps maintained by the U. S. Bureau of Standards, in cooperation with similar custodians in France, Great Britain, and Germany. The International candle is a point source of light having an intensity of a definite fraction of this standard intensity.

ELECTRIC UNITS. Three systems of electric and magnetic units are in general use, viz., (1) the cgs electrostatic system, (2) the cgs electromagnetic system, and (3) the practical system. In the cgs electrostatic system the dielectric coefficient, k, of air* at 0 deg cent and 760 mm mercury pressure is arbitrarily chosen as unity. In the cgs electromagnetic system the magnetic permeability of air under the same standard conditions is arbitrarily chosen as unity. In the practical system a concrete standard of the unit of resistance (called the ohm) and of the unit of current (ampere) is arbitrarily chosen (see below); the unit of resistance is closely equal to 10^9 times the unit of resistance in the cgs electromagnetic system and the unit current is approximately 0.1 that in the latter system. Occasionally other (special) systems are used, most of which are designed to get rid of a factor 4π which frequently appears in the usual systems. The most popular of these others is the Heaviside–Lorentz system in which the unit of electric charge is $1/\sqrt{4\pi}$ of the unit in the electrostatic system. (See MKS system.)

Use of the Prefixes "Stat" and "Ab." To designate the electric and magnetic units in the electrostatic and electromagnetic systems of units respectively, the prefixes "stat" and "ab" may be used with the name of the corresponding practical unit. For example, the cgs electrostatic unit of quantity may be called the statcoulomb and the cgs electromagnetic unit of quantity may be called the abcoulomb, etc.†

Relations among the Three Systems of Electrical Units. The fundamental relations, experimentally determined, between the cgs electrostatic and the cgs electromagnetic system is that 1 abfarad = 8.9878×10^{20} statfarads, which may be approximated for engineering purposes to

$$1 \text{ abfarad} = 9 \times 10^{20} \text{ statfarads}$$

which, as a consequence of the definition of the various terms, is equivalent to

$$1 \text{ abcoulomb} = 3 \times 10^{10} \text{ statcoulombs}$$

the erg being the unit of energy in both systems. Rigorously,

$$1 \text{ abcoulomb} = 2.9979 \times 10^{10} \text{ statcoulombs}$$

(See the article by Birge, *Rev. of Mod. Phys.*, Vol. 1, p. 1, July 1929.)

The fundamental relations between the cgs electromagnetic system and the practical system are

$$1 \text{ abcoulomb} = 10 \text{ coulombs}$$
$$1 \text{ erg} = 10^{-7} \text{ watt-second or joule}$$

the erg being the unit of energy in the cgs electromagnetic system and the joule (or watt-second) that in the practical system.

Practical Electrical Units. The legal units of electrical measure in the United States are given in an Act of Congress, July 12, 1894. Unfortunately, the units there defined are not consistent with one another; for example, the unit of power (watt) there given is not equal to the unit of power derived from the units of current (ampere) and voltage (volt)

* Rigorously, k of free or empty space is chosen unity; for air at 0 deg cent and 76 cm mercury pressure $k = 1.000585$; see International Critical Tables, Vol. 6, p. 77, for the value of k for air under various conditions.

† This abcoulomb, the unit of quantity of electricity in the electromagnetic system, should not be confused with an "absolute coulomb," which is a unit closely equal to the coulomb and is what the latter would be if 1 international or practical ohm equaled *exactly* 10^9 abohms and 1 ampere equaled *exactly* 0.1 abamp. For engineering purposes, the difference between an absolute coulomb and a coulomb is negligible.

as defined in the Act. Recently an amendment to the Treaty on Weights and Measures has given control of the electrical units to the International Committee on Weights and Measures, and within a few years the practical units in use in the United States will be defined in terms of the cgs electromagnetic units:

$$1 \text{ ohm} = 10^9 \text{ abohms and } 1 \text{ ampere} = 0.1 \text{ abampere}$$

At present the practical units (the so-called international units) are based on the following two definitions:

The unit of resistance is the (international) ohm and is equal to the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice, 14.4521 grams in mass, of a constant cross-sectional area and 106.300 cm in length.

The unit of current is the (international) ampere and is equal to the unvarying electric current which, when passed through a solution of nitrate of silver in accordance with certain specifications, deposits silver at the rate of 0.00111800 gram per second.

The unit of electromotive force, the (international) volt, is derived from the above by Ohm's law. Other international units are derived from these.

The reason for adopting these units is that it has been considered easier and more accurate to make electrical comparisons with these standards than to make absolute measurements in terms of fundamental (cgs electromagnetic) units. However, though it is comparatively easy to set up secondary standards of resistance from the primary standard defined above, it is not practical to set up secondary standards of current. Instead, the Weston normal cell is used as a standard of voltage, its voltage being determined from the primary standards of resistance and current above, and secondary standards of voltages (standard cells) are used. It will be seen from the data below (from Birge, cited above) that for practical purposes

$$\begin{aligned}
&1 \text{ ohm} &&= 10^9 \text{ abohms and } 1 \text{ ampere} = 0.1 \text{ abampere}\\
&1 \text{ international ohm} &&= 1.00051 \times 10^9 \text{ abohms}\\
&1 \text{ international ampere} &&= 0.99995 \times 0.1 \text{ abampere}\\
&1 \text{ international volt} &&= 1.00046 \times 10^8 \text{ abvolts}\\
&1 \text{ international joule} &&= 1.0004 \text{ absolute joules}\\
&\text{Weston normal cell voltage} &&= 1.01830 \text{ international volts}
\end{aligned}$$

The Act of 1894 defined the international ohm as above, but defined the ampere as 0.1 abampere. These units give rise to the so-called "semi-absolute" system, which is seldom used. For further details, see Circular 60 of the Bureau of Standards and references in the article by Birge cited above.

THE MKS SYSTEM OF UNITS. In 1904 Giorgi proposed a system of units in which the fundamental units were the meter, the kilogram, the second, and the ohm. If, using this system of fundamental units, the permeability of free space is taken as $\mu_0 = 4\pi \times 10^{-7}$ henry per meter, the equations of electricity and magnetism, using the practical units, become equations without factors such as 10^8, etc. Such a system is similar to the so-called absolute systems such as the cgs electromagnetic and the cgs electrostatic systems. It follows from the theory of radiation of electromagnetic waves that the dielectric coefficient $\epsilon_0 = \dfrac{1}{\mu_0 c^2}$, where c is the ratio of electrostatic to electromagnetic units, which can be taken as the velocity of light in free space.

The International Committee of Weights and Measures at its meeting in October 1935 at Sèvres, France, decided that the actual substitution of this absolute system of electrical units for the international system shall take place on January 1, 1940.

The units are then defined by a set of definitions such as follows:

(a) **Ampere.** The ampere is the constant current which, maintained in two parallel rectilinear conductors of infinite length separated by a distance of 1 meter, produces between these conductors a force equal to 2×10^{-7} mks (meter-kilogram-second) units of force per meter of length.

(b) **Volt.** The volt is the difference of electrical potential between two points of a conductor carrying a constant current of 1 ampere when the power dissipated between these points is equal to 1 mks unit of power (watt).

(c) **Coulomb.** The coulomb is the quantity of electricity transported each second by a current of 1 ampere.

(d) **Ohm.** The ohm is the electrical resistance between two points of a conductor when a constant difference of potential of 1 volt, applied between these points, produces in the conductor a current of 1 ampere, the conductor not being the seat of an electromotive force.

(e) **Weber.** The weber is the magnetic flux which, traversing a circuit of a single turn, would produce an electromotive force of 1 volt, if brought to zero in 1 second with uniform diminution.

(f) **Henry.** The henry is the inductance of a closed circuit in which an electromotive force of 1 volt is produced when the electric current traversing the circuit varies uniformly at the rate of 1 ampere per second.

(g) **Farad.** The farad is the electrical capacitance between the armatures of which appears an electrical difference of potential of 1 volt, when charged with 1 coulomb of electric quantity.

The original Giorgi mks system chose the ohm as the fourth fundamental unit. This choice has not been confirmed. The electrical fundamental unit could be almost any of the electrical units. No particular unit has as yet been chosen as fundamental. The preferences seem to be divided between the ampere, the ohm, the permeability, and the coulomb.

The original Giorgi mks system chose $\mu_0 = 4\pi 10^{-7}$, the 4π factor causing the electromagnetic formulas expressing rectilinear symmetry, such as the Maxwell equations, to be free of the factor 4π, and the electromagnetic formulas expressing circular symmetry, such as Coulomb's law, to contain the factor 4π. Such a system is called a rationalized system as contrasted with a non-rationalized system, examples of which are the electromagnetic and the electrostatic cgs systems. The non-rationalized mks system corresponding to the original Giorgi system is defined by the choice of $\mu_0 = 10^{-7}$. This changes the values of some of the units as shown in the table below.

These two questions, namely, the choice of the fundamental unit and the question of rationalization, will probably be decided before the official substitution date, January 1, 1940. The choice of the fundamental unit will be made in such a way as to conform with the definitions given above so that the units will not be changed. The question of rationalization will change the value of a few of the units by a factor 4π or $1/4\pi$ as shown below.

Rationalized MKS Units and Corresponding CGS Electromagnetic Units

Metric Multiples

10^6 microns = 10^3 millimeters = 10^2 centimeters = 10 decimeters = 1 meter = 10^{-1} dekameter = 10^{-2} hectometer = 10^{-3} kilometer = 10^{-4} myriameter = 10^{-6} megameter = 10^{10} Angstrom Units.

Land Measure

7.92 inches = 1 link
25 links = 1 rod = 16.5 feet = 5.5 yards (1 rod = 1 pole = 1 perch)
4 rods = 1 chain (Gunther's) = 66 feet = 22 yards = 100 links
10 chains = 1 furlong = 660 feet = 220 yards = 1000 links = 40 rods
8 furlongs = 1 mile = 5280 feet = 1760 yards = 8000 links = 320 rods = 80 chains

Ropes and Cables

2 yards = 1 fathom   120 fathoms = 1 cable's length

Nautical Measure

6080.27 feet = 1 knot = 1 nautical mile = 1.15156 statute miles
3 nautical miles = 1 league (U. S.)   3 statute miles = 1 league (Gr. Britain)

(NOTE.—A knot, or nautical mile, is the length of a minute of longitude of the earth at the equator at sea level. The British Admiralty uses the round figure of 6080 feet. The word "knot" is frequently used also to denote "nautical miles per hour.")

Miscellaneous

3 inches = 1 palm   9 inches = 1 span
4 inches = 1 hand   2 1/2 feet = 1 military pace

Metric Multiples

10 milliliters	= 1 centiliter	= 0.338 fluid ounce
10 centiliters	= 1 deciliter	= 0.845 liquid gill
10 deciliters	= 1 liter	= 1.0567 liquid quarts
10 liters	= 1 dekaliter	= 2.6417 liquid gallons
10 dekaliters	= 1 hectoliter	= 2.8375 U. S. bushels
10 hectoliters	= 1 kiloliter (or stere)	= 28.375 U. S. bushels

Cubic Measure

1 cord of wood = a pile cut 4 feet long, piled 4 feet high and 8 feet on the ground = 128 cubic feet

1 perch of stone = a quantity 1 $^1/_2$ feet thick, 1 foot high and 16 $^1/_2$ feet long = 24 $^3/_4$ cubic feet

(NOTE.—A perch of stone is, however, often computed differently in different localities; thus, in most if not all of the States and Territories west of the Mississippi, stonemasons figure rubble by the perch of 16 $^1/_2$ cubic feet. In Philadelphia, 22 cubic feet are called a perch. In Chicago, stone is measured by the cord of 100 cubic feet. Check should be made against local practice.)

Board Measure

In board measure, boards are assumed to be one inch in thickness. Therefore, feet board measure of a stick of square timber = length in feet × breadth in feet × thickness in inches.

Shipping Measure

For register tonnage or measurement of the entire internal capacity of a vessel, it is arbitrarily assumed, to facilitate computation, that:

100 cubic feet = 1 register ton

For the measurement of cargo:

40 cubic feet = 1 U. S. shipping ton = 32.143 U. S. bushels
42 cubic feet = 1 British shipping ton = 32.703 Imperial bushels

Dry Measure

One U. S. Winchester bushel contains 1.2445 cubic feet or 2150.42 cubic inches. It holds 77.601 pounds distilled water at 62° F.

(NOTE.—The above is a *struck* bushel. A *heaped* bushel in general equals 1 $^1/_4$ struck bushels, although for apples and pears it contains 1.2731 struck bushels = 2737.72 cubic inches.)

One U. S. gallon (dry measure) = $^1/_8$ bushel and contains 268.8 cubic inches.

(NOTE.—This is not a legal U. S. *dry measure* and therefore is given for comparison only.)

One British Imperial bushel contains 1.2843 cubic feet or 2219.36 cubic inches. It holds 80 pounds distilled water at 62° F.

One British Imperial gallon = $^1/_8$ Imperial bushel and contains 277.42 cubic inches.

1 Winchester bushel = 0.9694 Imperial bushel
1 Imperial bushel = 1.032 Winchester bushels

Same relations as above maintain for gallons (dry measure)

(NOTE.—1 U. S. gallon (dry) = 1.164 U. S. gallons (liquid)).

U. S. Units

2 pints	= 1 quart	=	67.2 cubic inches
4 quarts	= 1 gallon * = 8 pints	=	268.8 cubic inches
2 gallons*	= 1 peck = 16 pints = 8 quarts	=	537.6 cubic inches
4 pecks	= 1 bushel = 64 pints = 32 quarts = 8 gallons*	=	2150.42 cubic inches

1 cubic foot contains 6.428 gallons (dry measure)*

Liquid Measure

One U. S. gallon (liquid measure) contains 231 cubic inches. It holds 8.336 pounds distilled water at 62° F.

One British Imperial gallon contains 277.42 cubic inches. It holds 10 pounds distilled water at 62° F.

1 U. S. gallon (liquid) = 0.8327 Imperial gallon
1 Imperial gallon = 1.201 U. S. gallons (liquid)

(NOTE.—1 U. S. gallon (liquid) = 0.8594 U. S. gallon (dry)).

U. S. Units

4 gills	= 1 pint	=	16 fluid ounces
2 pints	= 1 quart = 8 gills	=	32 fluid ounces
4 quarts	= 1 gallon = 32 gills = 8 pints	=	128 fluid ounces

1 cubic foot contains 7.4805 gallons (liquid measure)

Apothecaries' Fluid Measure

60 minims = 1 fluid drachm. 8 drachms = 1 fluid ounce

In the U. S. a fluid ounce is the 128th part of a U. S. gallon, or 1.805 cu in. or 29.58 cu cm. It contains 455.8 grains of water at 62° F. In Great Britain the fluid ounce is 1.732 cu in. and contains 1 ounce avoirdupois (or 437.5 grains) of water at 62° F.

* The *gallon* is not a U. S. legal *dry measure*.

* Usually called "knots."

The Miner's Inch

(Used in Measuring Flow of Water)

An Act of the California legislature, May 23, 1901, makes the standard miner's inch 1.5 cu ft per minute, measured through any aperture or orifice.

The term Miner's Inch is more or less indefinite, for the reason that California water companies do not all use the same head above the center of the aperture, and the inch varies from 1.36 to 1.73 cu ft per minute, but the most common measurement is through an aperture 2 in. high and whatever length is required, and through a plank 1 1/4 in. thick. The lower edge of the aperture should be 2 in. above the bottom of the measuring-box, and the plank 5 in. high above the aperture, thus making a 6-in. head above the center of the stream. Each square inch of this opening represents a miner's inch, which is equal to a flow of 1.5 cu ft per minute.

* These same conversion factors apply to the *gravitational* units of force having the corresponding names. The dimensions of these units when used as gravitational units of force are MLT^{-2}; see table for *Force*.

† Avoirdupois pounds and ounces.

Metric Multiples

10^6 micrograms = 10^3 milligrams = 10^2 centigrams = 10 decigrams = 1 gram = 10^{-1} dekagram = 10^{-2} hectogram = 10^{-3} kilogram = 10^{-4} myriagram = 10^{-6} megagram

Avoirdupois Weight

(Used Commercially)

27.343 grains	= 1 drachm
16 drachms	= 1 ounce (oz) = 437.5 grains
16 ounces	= 1 pound (lb) = 7000 grains
28 pounds	= 1 quarter (qr)
4 quarters	= 1 hundredweight (cwt) = 112 pounds
20 hundredweight	= 1 gross or long ton *
2000 pounds	= 1 net or short ton

(* NOTE.—The long ton is used by the U. S. custom-houses in collecting duties upon foreign goods. It is also used in freighting coal and selling it wholesale.)

14 pounds	= 1 stone; 100 pounds = 1 quintal

Troy Weight

(Used in weighing gold or silver)

24 grains	= 1 pennyweight (dwt)
20 pennyweights	= 1 ounce (oz) = 480 grains
12 ounces	= 1 pound (lb) = 5760 grains

The grain is the same in Avoirdupois, Troy and Apothecaries' weights. A carat, for weighing diamonds = 3.086 grains = 0.200 gram. (International Standard, 1913.)

1 pound troy	= .8229 pound avoirdupois
1 pound avoirdupois	= 1.2153 pounds troy

Apothecaries' Weight

(Used in compounding medicines)

20 grains = 1 scruple (℈)
3 scruples = 1 drachm (ʒ) = 60 grains
8 drachms = 1 ounce (℥) = 480 grains
12 ounces = 1 pound (lb) = 5760 grains

The grain is the same in Avoirdupois, Troy and Apothecaries' weights.

1 pound apothecaries = 0.82286 pound avoirdupois
1 pound avoirdupois = 1.2153 pounds apothecaries

* See note at the bottom of Table 43.

† Mean calorie and Btu used throughout. One gram-calorie = 0.001 kilogram-calorie; one Ostwald calorie = 0.01 kilogram-calorie.

The IT cal, 1000 international steam-table calories, has been defined as the 1/860th part of the international kilowatthour (see *Mechanical Engineering*, Nov., 1935, p. 710). Its value is very nearly equal to the mean kilogram-calorie, 1 IT cal = 1.00037 kilogram-calories (mean). 1 Btu = 251.996 IT cal.

‡ Absolute joule, defined as 10^7 ergs. The international joule, based on the international ohm and ampere, equals 1.0003 absolute joules.

Webers per square inch	6.452×10^{-8}	10^{-8}	6.452	1

* The name "gauss" is sometimes used for the unit of magnetic field intensity (1 gauss = 1 gilbert per cm). Since flux density = permeability × field intensity ($B = \mu H$) these two quantities have the same units if μ is considered dimensionless, just as 1 abhenry = μ × 1 cm hence the occasional name centimeter for an abhenry. The A.I.E.E. sanctions "gauss" for both B and H; physicists usually do not. In 1930 the International Electrotechnical Commission, of which the U. S. National Committee is the electrical standards committee of the American Standards Association, adopted the following names for units in the cgs electromagnetic system: Magnetomotive force, gilbert; magnetizing force, oersted; magnetic flux, maxwell; magnetic flux density, gauss. The name oersted has been used for a unit of reluctance in the U. S.

Gilberts per centimeter	12.57	1.257	0.4950	1

* Called "oersteds" by the I.E.C. (1930). See footnote of Table 56 on "Magnetic Flux Density."

Table 33. Specific Heat $[L^2T^{-2}t^{-1}]$

(t = temperature)

To change specific heat in gram-calories per gram per degree Centigrade to the units given in any line of the following table, multiply by the factor in the last column.

Unit of Heat or Energy	Unit of Mass	Temperature Scale*	Factor
Gram-calories	Gram	Centigrade	1
Kilogram-calories	Kilogram	Centigrade	1
British thermal units	Pound	Centigrade	1.800
British thermal units	Pound	Fahrenheit	1.000
Joules	Gram	Centigrade	4.186
Joules	Pound	Fahrenheit	1055.
Kilowatt-hours	Kilogram	Centigrade	1.163×10^{-3}
Kilowatt-hours	Pound	Fahrenheit	2.930×10^{-4}

* Temperature conversion formulas:

t_c = temperature in Centigrade degrees
t_f = temperature in Fahrenheit degrees
1 deg fahr = (5/9) deg cent.
$t_c = \frac{5}{9}(t_f - 32)$
$t_f = \frac{9}{5}t_c + 32$

Table 34. Thermal Conductivity $[MLT^{-3}t^{-1}]$

(t = temperature)

To convert thermal conductivity, in gram-calories transmitted per second from one face of a cube 1 cm on edge to the opposite face per degree Centigrade temperature difference between these faces, to the units given in any line of the following table, multiply by the factor in the last column.

Units of				Temperature Scale	Factor
Heat	Area	Thickness	Time		
Gram-calories	cm^2	cm	second	Centigrade	1
Kilogram-calories	m^2	cm	hour	Centigrade	3.6×10^4
British thermal units	ft^2	inch	hour	Fahrenheit	2903.
Joules	cm^2	cm	second	Centigrade	4.186
Joules	ft^2	inch	second	Fahrenheit	850.6
Kilowatt-hours	m^2	cm	hour	Centigrade	41.86
Kilowatt-hours	ft^2	inch	hour	Fahrenheit	0.8506

16. GAGES

Sheet Metal Gages

The important sheet metal gages in use in the United States are: the United States Standard Gage for sheet and plate iron and steel, the American Wire Gage (also called the Brown and Sharpe W.G.) for copper, aluminum, and brass and other non-ferrous alloys, the Tin Plate Gage, the Galvanized Sheet Gage, the American Zinc Gage, and the Birmingham Wire (or Stubs' Iron Wire) Gage. In Canada and England the Birmingham Gage (different from the Birmingham Wire Gage) and the Imperial Standard Wire Gage (S.W.G.) are used. Still other gages are used elsewhere. In Japan standard thickness of sheet metal is denoted by the thickness in millimeters. A standard Decimal Gage, in which the standard thicknesses are denoted by decimal parts of an inch and not by gage numbers, has been used in the United States. Copper sheets may be obtained with thicknesses any integral multiple of $^1/_{16}$ of an inch up to 2 inches. Heavy copper sheets may be obtained in definite weights per square foot. Each ounce of weight is equivalent to approximately 0.001352 inch thickness. Lead is usually ordered in this manner, each pound being equivalent to approximately 0.017 inch thickness.

The United States Standard Gage for sheet iron and steel (Act of Congress, March 3, 1893; formerly the legal standard for duties) is a *weight* gage based on a density for wrought iron of 480 pounds per cubic foot. Since 1893, steel (density of 489.6 lb per cu ft) has come into general use. A given gage number of this gage represents a fixed weight per unit area, hence a steel sheet will have a smaller thickness than a wrought iron sheet of the same gage number (but monel metal sheets are rolled to the thickness given for wrought iron to without regard to weight, which is about 552.2 lb per cu ft. Practice among steel manufacturers is irregular, some keeping the *thickness* constant for a given gage number irrespective of weight. If this practice is followed, the weight per square foot and per square meter given in the second and third columns of Table 36 will vary, whereas thickness will remain that given for wrought iron.

The American Wire Gage specifies thicknesses without regard to weight. For the basis of this gage see the next section (Wire Gages), where are also given the Birmingham W.G. and the S.W.G.

Tables of Thickness and Weight corresponding to United States Standard gage and American Wire gage numbers are shown in Tables 36 and 37. These tables are taken from Circular No. 391 of the Bureau of Standards, in which are given all the gages mentioned above and the tolerances customary in commerce. A committee of the American Standards Association is now working (1936) on the standardization of sheet metal gages.

Table 36. United States Standard Gage * for Sheet and Plate Iron and Steel, and Its Extension †

* Assumed specific gravities or densities in grams per cubic centimeter; Copper, 8.89; Aluminum, 2.71; brass, 8.47.

Wire Gages

The sizes of wires having a diameter less than 1/2 inch are usually stated in terms of certain arbitrary scales called "gages." The size or gage number of a solid wire refers to the cross-section of the wire perpendicular to its length; the size or gage number of a stranded wire refers to the total cross-section of the constituent wires, irrespective of the pitch of the spiraling. Larger wires are usually described in terms of their area expressed in circular mils. A circular mil is the area of a circle 1 mil in diameter, and the area of any circle in circular mils is equal to the square of its diameter in mils.

There are a number of wire gages in use, the principal ones being the following:

American or Brown and Sharpe Wire Gage.—This gage is the one commonly used in the United States for copper, aluminum and resistance wires. The gage is designated by either of the abbreviations A.W.G. or B. & S.

Basis of the A.W.G. or B. & S. Gage.—The diameters of wires having successive numbers on this gage are in the ratio of $\sqrt[39]{92}$ (= 1.1229 approx.) to 1, and the No. 36 wire has a diameter of 5 mils. No. 35 A.W.G., therefore, has a diameter of $5 \times 1.1229 = 5.61$ mils and so on until No. 0000 is reached, having a diameter of 460 mils.

The ratio $\sqrt[39]{92}$ is approximately equal to $\sqrt[6]{2}$, which is 1.1225. This circumstance makes it possible to have a group of wires of regular gage size with an aggregate area approximately equal to that of another regular gage size. For example, a reduction of three gage numbers (as from gage No. 36 to No. 33) results in a new gage number representing a diameter approximately $\sqrt{2}$ times that represented by the original gage number—or an area approximately two times as great.

The following approximate relations are also useful:

An increase of 1 in the number increases the resistance 25 per cent.
An increase of 2 in the number increases the resistance 60 per cent.
An increase of 3 in the number increases the resistance 100 per cent.
An increase of 10 in the number increases the resistance 10 times.

A No. 10 A.W.G. copper wire has the following approximate characteristics:

Ohms per 1000 feet	1
Circular mils area	10,000
Weight, pounds per 1000 feet	32

A No. 10 A.W.G. aluminum wire has the following approximate characteristics:

Ohms per 1000 feet	1.6
Circular mils area	10,000
Weight, pounds per 1000 feet	9.5

Remembering these rules it is easy to find the approximate size, resistance, area, or weight of any size wire. For example, a No. 12 A.W.G. copper wire has a resistance of 1 plus 60 per cent = 1.6 ohms per 1000 ft approximately. Its area, being inversely as its resistance, is $10{,}000/1.6 = 6250$ circular mils; its diameter is therefore $\sqrt{6250} = 79$ mils and its weight, $32/1.6 = 20$ pounds per 1000 feet.

U. S. Steel Wire Gage.—This gage, known also as the "Washburn and Moen," "Roebling," "American Steel and Wire Co.'s gage," is the one usually employed in the United States for steel and iron wire. It is frequently abbreviated "S.W.G.," but to avoid confusion with the British Standard Wire Gage (*see below*) it should be abbreviated "Stl. W.G." or "A. (steel) W.G."

Birmingham (or Stubs' Iron) Wire Gage.—This gage is still used in the United States for some purposes, e.g., to designate the size of brass wire, and is also employed to a limited extent in Great Britain. It is usually abbreviated "B.W.G." It is sometimes referred to as the "Stubs' Iron Wire Gage," but it should not be confused with the Stubs' Steel Wire Gage.

British Standard Wire Gage.—This gage, usually called simply the "Standard Wire Gage," and abbreviated "S.W.G." is also known as the "New British Standard" (abbreviated "N.B.S."), the English Legal Standard, or the Imperial Wire Gage, and is the legal standard of Great Britain for all wires, as fixed by order in Council, August 23, 1883. It was constructed by modifying the Birmingham Wire Gage, so that the differences between successive diameters were the same for short ranges, i.e., so that a graph representing the diameters consists of a series of a few straight lines.

Edison Wire Gage.—The size of a wire on this gage is equal to its cross-sectional area in circular mils divided by 1000. For example, a solid wire 0.2 inch in diameter has the number $(200)^2/1000 = 40$. This gage is now rarely used.

Metric Wire Gage.—The gage number is ten times the diameter in millimeters.

Other Gages.—In addition wire sizes are sometimes specified in terms of the "Old English Wire Gage," known also as the "London Gage," and the "Stubs' Steel Wire Gage." The Old English Wire Gage is the same as B.W.G. for all gage numbers under 20.

Comparison of Wire Gages.—A comparison of the different gages, in terms of the diameters (in mils or thousandths of an inch) of solid wires corresponding to the various numbers, is given in Table 38. The cross-section in circular mils is the square of the diameter in mils.

Table 38. Comparison of Wire Gage Diameters in Mils
(Bureau of Standards, Circulars No. 31 and No. 67)

Gage No.	American wire gage (B. & S.)	Steel wire gage	Birmingham wire gage (Stubs')	Old English wire gage (London)	Stubs' steel wire gage	(British) Standard wire gage	Metric gage *	Gage No.

* For diameters corresponding to metric gage numbers, 1.2, 1.4, 1.6, 1.8, 2.5, 3.5, and 4.5, divide those of 12, 14, etc., by ten.

SYMBOLS AND ABBREVIATIONS

17. ABBREVIATIONS FOR ENGINEERING TERMS

Note: This list is a selection of American Tentative Standard abbreviations, for scientific and engineering terms, recommended by the American Standards Association. (See ASA, Z10i—1932.)

Absolute	abs
Acre	acre
Alternating-current (as adjective)	a-c
Ampere	amp
Ampere-hour	amp-hr
Angstrom unit	A
Atomic weight	at. wt
Atmosphere	atm
Average	avg
Avoirdupois	avdp
Barometer	bar.
Barrel	bbl
Baumé	Bé
Boiler pressure	bp
Boiling point	bp
Brake horsepower	bhp
Brake horsepower-hour	bhp-hr
Brinell hardness number	Bhn
British thermal unit	Btu or B
Calory	cal
Candlepower	cp
Centigram	cg
Centiliter	cl
Centimeter	cm
Centimeter-gram-second (system)	cgs
Chemically pure	cp
Circular	cir
Circular mils	cir mils
Coefficient	coef
Cologarithm	colog
Concentrate	conc
Conductivity	cond
Constant	const
Cord	cd
Cosecant	csc
Cosine	cos
Cotangent	ctn
Coulomb	spell out
Counter electromotive force	counter emf
Cubic	cu
Cubic centimeter	cu cm, cm^3, cc
Cubic foot	cu ft
Cubic inch	cu in.
Cubic meter	cu m or m^3
Cubic yard	cu yd
Decibel	db
Degree	deg or °
Degree Centigrade	C
Degree Fahrenheit	F
Degree Kelvin	K
Degree Réaumur	R
Diameter	diam
Direct-current (as adjective)	d-c
Dozen	doz
Dram	dr
Efficiency	eff
Electric	elec
Electromotive force	emf
Equation	eq
External	ext
Farad	spell out
Foot	ft
Foot-candle	ft-c
Foot-Lambert	ft-L
Foot-pound	ft-lb
Foot-pound-second (system)	fps
Freezing point	fp
Frequency	spell out
Fusion point	fnp
Gallon	gal
Grain	spell out
Gram	g
Gram-calory	g-cal
Henry	h
Horsepower	hp
Horsepower-hour	hp-hr
Hour	hr
Hundred	C
Hyperbolic sine	sinh
Hyperbolic cosine	cosh
Hyperbolic tangent	tanh
Inch	in.
Inch-pound	in-lb
Internal	int
Joule	j
Kilocycle	kc
Kilogram	kg
Kilogram-meter	kg-m
Kiloliter	kl
Kilometer	km
Kilovolt	kv
Kilovolt-ampere	kva
Kilowatt	kw
Kilowatthour	kwhr
Lambert	L
Latitude	lat
Linear foot	lin ft
Liter	l
Liquid	liq
Logarithm (common)	log
Logarithm (natural)	$\log_e$ or ln
Longitude	long.
Lumen	l
Lumen-hour	l-hr
Magnetomotive force	mmf
Mass	spell out
Mathematics (ical)	math
Maximum	max
Melting point	mp
Meter	m
Meter-kilogram	m-kg
Mho	spell out
Microampere	μa or mu a
Microfarad	μf or mu f
Micromicron	$\mu\mu$ or mu mu
Micron	μ mu
Microwatt	μw or mu w
Mile	spell out
Milliampere	ma
Millifarad	mf
Milligram	mg
Millihenry	mh
Milliliter	ml
Millimeter	mm
Millimicron	mμ or m mu
Million	spell out
Millivolt	mv

Abbreviations for Engineering Terms—*Continued*

Minimum	min
Minute	min
Minute (angular measure)	′
Ohm	spell out
Ounce	oz
Ounce-foot	oz-ft
Once-inch	oz-in.
Peck	pk
Pint	pt
Potential	spell out
Pound	lb
Pound-foot	lb-ft
Pound-inch	lb-in.
Pounds per square foot	lb per sq ft
Pounds per square inch	lb per sq in.
Power factor	spell out
Quart	qt
Radian	spell out
Reactive kilovolt-ampere	rkva
Reactive volt-ampere	rva
Revolutions per minute	rpm
Revolutions per second	rps
Rod	spell out
Root mean square	rms
Secant	sec
Second	sec
Second (angular measure)	″
Sine	sin
Specific gravity	sp gr
Specific heat	sp ht
Spherical candle power	scp
Square	sq
Square centimeter	sq cm or cm^2
Square foot	sq ft
Square inch	sq in.
Square kilometer	sq km or km^2
Square meter	sq m or m^2
Square root of mean square	rms
Standard	std
Tangent	tan
Temperature	temp
Thousand	M
Ton	spell out
Versed sine	vers
Volt	v
Volt-ampere	va
Watt	w
Watthour	whr
Weight	wt
Yard	yd
Year	yr

18. LETTER SYMBOLS FOR ELECTRICAL QUANTITIES

(Adopted by the Board of Directors, A.I.E.E., October 18, 1928)

Name of Quantity	Symbol
1. Admittance	Y, y
2. Angular frequency	ω
3. Angular velocity	ω
4. Capacitance	C
5. Capacity, electrostatic (*see* capacitance)	
6. Conductance	G, g
7. Conductivity	γ
8. Current	I, i
9. Difference of potential, electric (*see* note 4)	E, e
10. Dielectric constant	K or ϵ
11. Dielectric flux	Ψ
12. Dielectric flux density	D
13. Efficiency	η
14. Electric potential (*see* note 4)	E, e
15. Electrical tension (*see* voltage)	
16. Electromotive force	E, e
17. Electrostatic capacity (*see* capacitance)	
18. Electrostatic flux (*see* dielectric flux)	
19. Electrostatic flux density (*see* dielectric flux density)	
20. Energy	W
21. Flux density, electrostatic (*see* dielectric flux density)	
22. Flux density, magnetic (*see* magnetic flux density)	
23. Frequency	f
24. Impedance	Z, z
25. Inductance	L
26. Magnetic intensity	H
27. Magnetic flux	Φ
28. Magnetic flux density	B
29. Magnetomotive force	$\mathcal{F}$
30. Mutual inductance	M
31. Number of conductors or turns	N
32. Permeability	μ
33. Permeance	$\mathcal{P}$
34. Permittance (*see* capacitance)	
35. Period	T
36. Permittivity (*see* dielectric constant)	
37. Phase displacement	θ or φ
38. Power	P, p
39. Quantity, electric	Q, q
40. Quantity of electricity	Q, q
41. Reactance	X, x
42. Resistance	R, r
43. Resistivity	ρ
44. Reluctance	$\mathcal{R}$
45. Reluctivity	ν
46. Self-inductance	L
47. Susceptance	b
48. Speed of rotation	n
49. Voltage	E, e
50. Work	W

NOTES: 1. Where distinctions between maximum, instantaneous, effective (root-mean-square), and average values are necessary, E_m, I_m, P_m are recommended for maximum values; e, i, p for instantaneous values, E, I for effective (rms) values, and P for average value.

2. In accordance with the practice in other branches of engineering, it is recommended that quantities per unit volume, area, length, etc., be represented as far as practicable by lower-case letters corresponding to the capitals which represent the total quantities.

3. In print, vector or complex quantities should be represented by bold-face letters. In typing, overscoring may be used to indicate bold-face letters (vectors).

4. Where a distinction between electromotive force and difference of electric potential is desirable, the symbols E e, and V v, respectively, may be used.

19. SYMBOLS FOR POWER APPARATUS

(Approved by the Board of Directors, A.I.E.E., May 20, 1932)
(Approved by American Standards Association, September 1, 1933)

Name	One Line	Complete*
1. A-c Generator or Motor—Basic Symbol For motor, use "M" within symbol if necessary to distinguish.		
2. Induction Motor		
3. Induction Rotor with Slip Ring Rotor		
4. Synchronous Generator or Motor with Separately Excited Field		
5. Synchronous Converter (See also "D-c Generator or Motor")		
6. D-c Generator or Motor—Basic Symbol For motor, use "M" within symbol if necessary to distinguish.		
7. D-c Generator or Motor with Shunt and Series Field		
8. Direct Connected Units—Basic Symbol Use particular symbols and join as here shown.		
*9. Single-phase Two-winding Transformer — Basic Symbol***		
*10. Polyphase Two-winding Transformer—Basic Symbol***		
*11. Three-winding Transformer***		
*12. Auto-transformer***		
*13. Transformer with Taps***		
*14. Constant Current Transformer***		
*15. Current Transformer***		
*16. Potential Transformer***		
17. Induction Voltage Regulator		
18. Disconnecting Switch—Basic Symbol		
19. Knife Switch, Single-throw		
20. Disconnecting Switch, Group Operated		
21. Air Break Switch, Horn Gap, Group Operated		
22. Double-throw Switch		
23. Oil Circuit Breaker, Single-throw		
24. Oil Circuit Breaker, Double-throw		
25. Air Circuit Breaker		

Note: Use symbol () for windings of apparatus as required, and connect to suit particular case.

* The "complete" symbol is intended to illustrate the method of treatment for any desired polyphase combination rather than to show the exact symbol required.

*** This symbol has not been approved as American Standard because in radio symbols it is preferred to use looped lines to indicate the winding and in the case of iron core transformers to use parallel lines between the windings to indicate the iron core. At present these are irreconcilable.*

Name	One Line	Complete*
26. Fuse		
27. Resistor *This symbol has not been approved as American Standard because in radio symbols the symbol is*  *. At present theseareirreconcilable.*		
28. Rheostat		
29. Reactor		30. Capacitor *This symbol has not been approved as American Standard because in radio symbols the symbol is*  *. At present these are irreconcilable.*		

Name	One Line	Complete*
31. Lightning Arrester—Basic Symbol *This symbol has not been approved as American Standard because in railway symbols the symbol is*  *. At present these are irreconcilable.*		32. Pothead Cable Terminal		
33. Mercury Arc Rectifier		34. Battery Polarity should be indicated.		
35. Instrument Shunt		36. Lamp		
* The "complete" symbol is intended to illustrate the method of treatment for any desired polyphase combination rather than to show the exact symbol required.

Symbols for Instruments and Relays

Instruments

Relays

200 Relay—Basic Symbol	* R	**

Relay Function Designation

(For use with relay and oil circuit breaker symbols.)

201. Over-current		**
202. Over-voltage	V	**
203. Over-power	W	**
204. Under-current		**
205. Under-voltage	V	**
206. Under-power	W	**
207. Power Directional		**
208. Distance or Impedance, Non-directional	Z	**
209. Distance or Impedance, Directional	Z	**
210. Differential Current	X	**
211. Differential Power	X	**
212. Pilot Wire		**
213. Temperature		**
214. Phase Balance Current		**
215. For Ground Relay Application Add Ground Symbol to Relay Symbol, Thus		**

Relay Time Designations

(When necessary to establish time functions us the following in addition to function designations.)

250. Instantaneous—No Time Delay	Inst.	**
251. Inverse Time Delay	I.T.	**
252. Definite Time Delay	D.T.	**

Letter within circle indicates type of instrument if but one is used. If more than one instrument is used "I" appears within the circle with abbreviation alongside.

† For complete symbol show outline approximating that of rear view of actual device and indicate terminals in actual relative location, current terminals by open circles and potential terminals by solid circles. Scale range and type number may be marked adjacent to symbol, if desired.

‡ For use adjacent to instrument symbol.

* Relay designations appear beside the "R" circle. For system diagrams, current transformer symbols may be omitted and relay designations placed beside the oil circuit breaker symbol.

** For complete line symbol show outline approximating that of rear view of actual device and indicate terminals in actual relative location, current terminals by open circles and potential terminals by solid circles. Tripping circuit may be identified by representation of contacts within outline.

General Symbols for Maps and Connection Diagrams

Name	One Line	Complete
Wiring Diagrams †		
300. Conductors		301. Conductors, Crossing but not connected		302. Conductors, Crossing and Electrically Connected		
303. Bus (with Branches)		304. Conductors with Branches		
305. Ground Connection		

Name	Symbol
Winding Connections	
400. Two-phase, Three-wire	
401. Two-phase, Four-wire	
402. Three-phase, Delta (or Mesh)	
403 Three-phase Y (or Star)	
404. Three-phase Y (or Star) with Neutral Brought Out and Grounded	
405. Three-phase, zigzag	
406. Three-phase T	
407. Six-phase, Double Delta	
408. Six-phase, Hexagonal (or Chordal)	
409. Six-phase, Diametrical (or Star)	
410. Six-phase Diametrical (or Star) with Neutral Brought Out and Grounded	
Maps	
500. Generating Station	
501. Substation	
502. One or More Circuits Overhead	
503. One or More Circuits Underground	
504. Overhead Line on Pole	
505. Overhead Line on Tower	
506. Street Lamp	

† The thickness of the line varies according to the importance of the circuits; compare "Conductors" with "Bus," for example.

CONSTANTS

By Carl C. Chambers

20. PRINCIPAL PHYSICAL CONSTANTS AND RATIOS*

Velocity of light	$(2.99796 \pm 0.00004) \times 10^{10}$ cm sec^{-1}
Ratio of electrostatic to electromagnetic units	$(2.9971 \pm 0.0001) \times 10^{10}$ cm$^{1/2}$ sec$^{-1/2}$ (int ohms)$^{-1/2}$ $(2.9979 \pm 0.0001) \times 10^{10}$ cm sec^{-1} (in absolute units)
Volume of a perfect gas (0° C and normal atmospheric pressure)	$(22.4141 \pm 0.0008) \times 10^{3}$ cm^3 mole^{-1}
Normal atmospheric pressure	$(1.013249 \pm 0.000003) \times 10^{6}$ dynes cm^{-2}
45° atmospheric pressure	$(1.013199 \pm 0.000003) \times 10^{6}$ dynes cm^{-2}
Ice point (absolute scale)	273.18 ± 0.03° K
Mechanical equivalent of heat (20° C)	4.1813 ± 0.0006 abs joule cal^{-1}
Electrical equivalent of heat (20° C)	4.1796 ± 0.0007 int joule cal^{-1}
Faraday constant	96494 ± 5 int coulombs g-equiv^{-1}
Electronic charge	$(4.770 \pm 0.005) \times 10^{-10}$ abs-es unit $(1.5910 \pm 0.0016) \times 10^{-20}$ abs-em unit
Planck constant	$(6.547 \pm 0.008) \times 10^{-27}$ erg sec^{-1}
Acceleration of gravity	980.665 cm sec^{-2}
Electrochemical equivalent of silver	$(1.11800 \pm 0.00005) \times 10^{-3}$ g. (int coulombs)$^{-1}$
Wave-length of red cadmium line (15° C, normal atmospheric pressure)	6438.4696 I.A.†
Effective grating space of calcite (20° C)	$(3.0279 \pm 0.0010) \times 10^{-8}$ cm
Avogadro's number	$(6.064 \pm 0.006) \times 10^{23}$ mole^{-1}
Boltzmann constant	$(1.3708 \pm 0.0014) \times 10^{-16}$ erg deg^{-1}
Stefan-Boltzmann constant	$(5.735 \pm 0.011) \times 10^{-5}$ erg cm^{-1} deg^{-4} sec^{-1}
Mass of the electron	$(9.01 \pm 0.03) \times 10^{-28}$ g
Ratio of mass of H to mass of electron (measured by deflection)	1847 ± 2

* Values taken from Birge, *Rev. of Mod. Phys.*, Vol. 1, No. 1, p. 1 (July, 1929).

† This defines the international angstrom unit (I.A.). The unit is of the order of 1 part in several million different from 10^{-8} cm.

2. WEIGHTS (MASSES) OF MATERIALS

The density of any substance is the mass of that substance per unit volume. Or, using weight in the ordinary sense as equivalent to mass, the density may also be defined as the *weight* per unit volume. The numerical value of the density of any substance depends upon the unit in which the mass or weight is expressed and also upon the unit of volume used; see Units and Conversion Factors. However, it is quite common to state the density of a substance in grams per cubic centimeter, without naming the units, since when so expressed the density is numerically equal (practically) to the specific gravity.

The "specific gravity" of a substance is defined as the ratio of the weight (mass) per unit volume of that substance to the weight (mass), expressed in the same unit of an equal volume of water. To make such a statement exact the temperature of the water should be specified. There is no general agreement as to the temperature of reference, though water at 0 deg cent is commonly taken as the reference temperature. For gases, air at 0 deg cent and 760 mm mercury pressure is frequently taken as the reference substance instead of water.

VARIATION OF DENSITY OF WATER WITH TEMPERATURE. The following table gives the results of measurements by Thiesen, Scheel, and Diesselhorst (Landolt, Börnstein and Roth, Physikalisch-chemische Tabellin, 1913).

Table 1. Density of Water; Grams per CC

Example: The density of water at 33 deg cent is 0.99473.

WEIGHTS PER CUBIC FOOT AND SPECIFIC GRAVITY. In the following table are given the values of the density in pounds per cubic foot of the more commonly used substances. The specific gravity, or density in grams per cubic centimeter, corresponding to any weight per cubic foot w is equal to $w/62.43$; for the conversion factors necessary to convert these figures into densities for other units of mass and volume, see Units and Conversion Factors.

Table 2. Specific Gravity and Pounds per Cubic Foot of Various Materials at Room Temperatures

Specific Gravities all referred to water at 0 deg cent.
(See References at end of table)

CONDUCTOR MATERIALS

3. CLASSIFICATION

Theoretically the terms conductor and insulator are only relative. There is no sharp dividing line between them. For practical purposes, however, conducting materials are those selected to carry current in an electrical circuit and insulating materials are those chosen to restrict the current in the conductor to desired paths.

Conductors are mostly all metals, but there is a wide difference in conductivity (as much as 70 to 1 ratio in metals). They are usually separated into:

a. Good conductors such as copper, aluminum, silver.

b. Poor conductors (resistors) such as iron; alloys of nickel, iron, copper, chromium; and carbon products.

4. COPPER

(See also Electrochemical Processes, Industrial; Wires and Cables, Bare.) The following discussion applies primarily to copper for electrical conductors.

ROLLING-MILL PROCESSES. The refined copper comes to the rod mill in bars weighing about 200 lb each. These bars frequently have ridges along the sides, due to faults in castings, and the surface is often covered with a layer of oxide. They are heated in a furnace until sufficiently soft for rolling and are passed through a series of rolls diminishing in size until a rod of the proper diameter is obtained. The rod is then coiled up and immersed in a pickling liquid (10 per cent H_2SO_4) in order to dissolve the oxide formed during rolling. It is then washed.

WIRE-MILL PROCESSES. The rods having cooled are connected together by brazing and are drawn through a series of dies of decreasing diameter. The rod is lubricated by passing through a ball of tallow just before entering the die. Drawing the wire hardens the outside of the wire and increases its strength almost in proportion to the reduction in cross-sectional area. The smaller the wire, the larger the proportion of hardened metal, and hence the higher the tensile strength.

DEFECTS IN WIRE. One of the most serious defects in wire results from ridged bars. As the bar enters the rolls, these ridges are sometimes folded over, enclosing the oxidized surface or scale. Subsequent passes hide this fold, sometimes completely, but it remains a serious flaw even through the final drawing operations. Careless handling, uneven welding of the rods, and unequal temperature of the wire while passing through the dies will all produce noticeable effects in the quality of the finished wire, so that care throughout the mill is absolutely necessary for the best results.

It, therefore, appears that the most efficient wire must possess not only high conductivity but also the maximum torsion and tensile strength possible in commercial copper, and that to obtain these qualities it is necessary to use high-grade copper and to prevent an excess of cuprous oxide entering it at any stage of the manufacture.

ANNEALING. All wire when first drawn is more or less hard. It may be softened by annealing, i.e., by heating to a temperature between 450 and 600 deg cent. The hardness is not affected by the rate of cooling. Annealed copper has a crystalline structure, whereas hard-drawn copper consists of grains elongated in the direction of drawing.

OXYGEN-FREE HIGH-CONDUCTIVITY COPPER. A special grade of copper is available which is made under carefully controlled conditions. The atmosphere present in the furnace and the method of casting prevent entrance of oxygen and formation of copper oxide. Wire or other shapes made from this material exhibit much superior characteristics in two respects. The ductility, as evidenced in elongation, torsion and bending, is made greater. OFHC wire may be twisted two to three times as many turns as regular copper. This copper also may be subjected to the action of reducing gases at elevated temperatures (as in brazing) without the usual danger of embrittlement. Conductivity and tensile strength are the same as for tough pitch electrolytic copper. The fatigue resistance is apparently unchanged.

Because of the superior ductility of oxygen free copper, it is useful in difficult operations of deep drawing, spinning or edge bending. Where the embrittlement hazard must be avoided in welding, brazing, or hot working operations, this copper may be used to advantage, in spite of the higher cost.

Mechanical Properties

(See Wires and Cables, Bare.) The more important mechanical properties of copper are discussed in some detail below.

TENSILE STRENGTH AND ELONGATION OF SOFT ANNEALED COPPER. The tensile strength of soft annealed copper is about 30,000 to 33,000 lb per sq in. with an elongation of about 25 per cent (in 10 in.) at the fracture. It has no true elastic limit, permanent elongation being produced by very small loads.

TENSILE STRENGTH AND ELONGATION OF HARD-DRAWN COPPER. Modern hard-drawn copper is equally affected by drawing throughout the section, no hard skin being produced. According to D. R. Pye, hard-drawn copper in wires up to $^1/_2$-in. diameter varies in tensile strength with the diameter according to a linear law of the form

$$T = 70{,}000 - 45{,}000\,D$$

where T = tensile strength, pounds per square inch; and D = diameter of wire, inches.

The above constants agree approximately with the tables of the American Society for Testing Materials and represent values somewhat under those usually obtained.

The elongation at fracture is approximately represented by

$$E = 4\sqrt{D}$$

where E = per cent elongation at fracture.

Tests by G. C. Batson on 50-ft lengths of hard-drawn copper showed a tensile strength only $^1/_2$ per cent less than that of 10-ft lengths, a fact which indicates the material is very uniform.

MODULUS OF ELASTICITY OF HARD-DRAWN COPPER. The modulus of elasticity of hard-drawn copper varies somewhat with diameter, higher values being shown by small wires. The usual figure taken is 16×10^6 as an average for all copper forms.

COMPRESSION TEST. Copper of good quality does not fracture under compression; it yields and flattens. According to Thurston the resistance to compression may be calculated, within the limits $e < {}^1/_2$, from the formula

$$C = 145{,}000\sqrt[3]{e}$$

where C = resistance in pounds per square inch of original area, and e = fractional compression.

MISCELLANEOUS MECHANICAL PROPERTIES. The torsional strength, shearing strength, hardness, resistance to impact, and fatigue of copper are all discussed in Bureau of Standards Circular No. 73 on Copper.

Table 1. Typical Properties of Copper

	Brinell Hardness	Tensile Strength lb per sq in.	Yield Strength lb per sq in.	Elongation	Endurance Limit lb per sq in.
As Cast	36	30,000	17,000	45	6,000
Bars					
Soft	40	32,000	12,000	38	10,000
Hard	70	50,000	46,000	18	15,000
Sheet					
Soft	40	32,000	12,000	37	10,000
Hard	100	51,000	48,000	4	15,000
Wire					
Soft	..	38,000	12,000	36	10,000
Hard	..	60,000	39,000	3	15,000

DENSITY. The density of copper or, for all practical purposes, its specific gravity referred to water, is 8.89 at 20 deg cent. This is the value which has been adopted as standard by the American Institute of Electrical Engineers, and most other authorities in the past. Measurements by the Bureau of Standards, the Calumet & Hecla Smelting Works, and the Reichsanstalt have indicated this as a mean.

Conductivity and Resistivity

F. A. Wolff and J. H. Dellinger give the resistivities of 89 samples of commercial copper from 14 important refiners and wire manufacturers in this and other countries. The mean for annealed wire is: Resistivity in ohms per meter-gram at 20 deg cent = 0.15292; per cent conductivity = 100.25. (Per cent conductivity is computed on the basis of 100 per cent conductivity corresponding to the standard resistivity of 0.15328 ohm per meter-gram at 20 deg cent.)

CONDUCTIVITY OF HARD-DRAWN COPPER. The conductivity of hard-drawn No. 12 B. & S. wires was found to be less than the conductivity of annealed wires by a mean value of 2.7 per cent. The difference between the conductivity of annealed and hard-drawn wires increases as the diameter of the wire decreases. The minimum conductivity usually specified for annealed wire is 98 per cent. Resistivity of annealed wire is taken as 10.371 ohms per circular mil foot at 20 deg cent.

TEMPERATURE COEFFICIENT OF RESISTIVITY. It has been found by J. H. Dellinger (Bulletin 147, Bur. Standards, 1910, Vol. 7, No. 1) that the temperature coefficient of copper is proportional to the conductivity instead of being virtually a constant, as hitherto assumed. This fact may be expressed by saying that the change of resistivity per degree centigrade of a sample of copper is 0.000597 ohm per meter-gram or 0.00681 microhm per centimeter cube. The 20 deg cent temperature coefficient of a sample of copper is found by multiplying the per cent conductivity by 0.00393 and dividing by 100. These rules apply only to copper furnished for electrical use and to the temperature range of 10 to 100 deg cent over which the temperature coefficient was found to be linear. Table 2 gives the temperature coefficients α_T in the formula:

$$R_t = R_T[1 + \alpha_T(t - T)]$$

Table 2

Ohms per meter-gram at 20 deg cent	Per cent conductivity	α_0	α_{15}	α_{20}	α_{25}	α_{30}
0.16134	95	0.00403	0.00380	0.00373	0.00367	0.00360
0.15966	96	0.00408	0.00385	0.00377	0.00370	0.00364
0.15802	97	0.00413	0.00389	0.00381	0.00374	0.00367
0.15753	97.3	0.00414	0.00390	0.00382	0.00375	0.00368
0.15640	98	0.00417	0.00393	0.00385	0.00378	0.00371
0.15482	99	0.00422	0.00397	0.00389	0.00382	0.00374
0.15328	**100**	0.00427	0.00401	**0.00393**	0.00385	0.00378
0.15176	101	0.00431	0.00405	0.00397	0.00389	0.00382

The bold-face values in the table have been adopted as standard by the American Institute of Electrical Engineers.

5. ALUMINUM

The method of manufacturing aluminum wire is similar to that employed in making copper wire. Commercial conductors are generally made from aluminum having a purity of about 99.5 per cent.

PHYSICAL CHARACTERISTICS (COPPER, ALUMINUM, AND STEEL COMPARED). The weights of the different materials are as follows. For aluminum, copper, and steel stranded conductors 2 per cent is added to the wire weights.

Material	Weight in Pounds of One Million Circular Mils, 1000 Ft Long		Weight in Kilograms, of One Square Millimeter, One Kilometer Long	
	Wire	Cable	Wire	Cable
Aluminum	920	938	2.702	2.756
Copper	3029	3090	8.896	9.074
Steel	2640	2690	7.753	7.908

Modulus of elasticity of aluminum, 9,000,000 lb per sq in.
Modulus of elasticity of copper, 16,000,000 lb per sq in.
Modulus of elasticity of steel, 30,000,000 lb per sq in.

The following values are used for hard-drawn material:

Elastic limit of aluminum, 21,000 lb per sq in.
Elastic limit of copper, 30,000 lb per sq in.
Elastic limit of steel, 130,000 lb per sq in.
Ultimate stress of aluminum, 24,000 lb per sq in.
Ultimate stress of copper, 60,000 lb per sq in.
Ultimate stress of steel, 190,000 lb per sq in.

Coefficient of expansion of aluminum (per degree cent) 0.0000231
Coefficient of expansion of copper (per degree cent) 0.0000167
Coefficient of expansion of steel (per degree cent) 0.0000115

CONDUCTIVITY AND RESISTIVITY. The Aluminum Company of America gives, as the average of many thousands of separate determinations, the figure of 2.828 microhms per centimeter cube, or 17.002 ohms per circular mil foot, at 20 deg cent, as the resistivity of commercial aluminum wire. This corresponds to a conductivity of 61 per cent of the annealed copper standard.

EFFECT OF HARDNESS ON CONDUCTIVITY. The resistance of aluminum depends upon its hardness; for example, the resistance of aluminum wire of hardness corresponding to a tensile strength of about 20 kg per sq mm (28,500 lb per sq in.) is approximately 2 per cent greater than that of the same wire when thoroughly annealed, and consequently soft (H. M. Hobart).

In the tables of stranded conductors, the resistances are 2 per cent greater than the equivalent solid conductor. This allows for increase of length due to an average length of lay as recommended by the American Institute of Electrical Engineers.

In computing the resistances of Aluminum Cable Steel Reinforced no deduction is made for the conductance of the steel core.

TEMPERATURE COEFFICIENT OF RESISTIVITY. The 20 deg cent temperature coefficient of 61 per cent conductivity annealed aluminum wire is 0.00403 per degree centigrade, and the 0 deg cent coefficient is 0.00444. Grassi also found that the temperature coefficient of aluminum is proportional to its per cent conductivity (as is true also of copper).

Table 3. Comparison of Copper and Aluminum Wires for Equal Resistances per Unit Length

Item	Copper	Aluminum
Cost	1	$0.488 \times \frac{p}{P}$
Cross-section	1	1.61
Diameter	1	1.27
Weight	1	0.488
Breaking strength	1	0 64

p = unit price of aluminum wire.
P = unit price of copper wire.

DISADVANTAGE OF LOW TENSILE STRENGTH. The lower tensile strength of aluminum for equal length and conductance as compared with copper affects the cost of an aerial line in two ways: first, by making it necessary to erect the spans with a greater sag or less length in order to reduce the stresses, thereby either increasing the height or the number of poles; and second, by making it necessary to increase the distance between wires on account of the increased sag. The increase in the height of poles for the same spacing amounts to about 10 per cent (C. L. Johnson). Aluminum cables with steel core are now used and overcome these difficulties.

EFFECT OF LARGE ELONGATION OF ALUMINUM. The extraordinarily great elongation of aluminum enables it to withstand severe mechanical overloads by stretching and thus increasing the sag. However, in dealing with a single solid wire this cannot be relied on, as a scratch or a single imperfection will often cause the wire to break without any appreciable elongation. This is one reason why cables are to be preferred to single-wire conductors.

CORONA FORMATION. At very high potentials, such as 100,000 volts, aluminum conductors possess a marked advantage over copper in the lower corona loss due to their greater diameter for the same conductance.

MELTING OF ALUMINUM CABLES. Because of the lower melting point of aluminum (660 deg cent compared to 1085 deg cent for copper), it was once the opinion that aluminum transmission cables would be subject to more damage from flashover arcs on transmission lines. Recent tests have shown that aluminum cable and copper are equally good in resisting arcs. In some test cases it was noted that the arc spreads more on aluminum than on copper, and the effect was therefore less concentrated. Furthermore, the steel core provides ample strength even if the aluminum is badly burned.

ALUMINUM CONDUCTORS IN ELECTRICAL MACHINES. The use of aluminum in motors and generators, particularly for field coils, has been advantageous where weight is a primary consideration, as in railway motors. The coils must, however, either occupy more space or be operated at a higher temperature. The difficulty of making a satisfactory and permanent joint to other portions of the circuit, which may be of copper, has retarded the use of aluminum conductors in machines.

6. METALLIC RESISTOR MATERIALS

There are on the market a large number of alloy wires used for resistance purposes. They cover a wide range of resistivities, operating temperature limits, physical properties. temperature coefficient of resistance, and thermal emf. For detailed description of these products the catalogs of manufacturers should be consulted. In general, the trade-name products can be grouped in approximately ten classes of alloys. Table 4, naming a few

Table 4. Properties of Metals and Alloys Used in Resistors

7. CARBON CONTACT MATERIALS

Carbon and combinations of carbon and metal are commonly used as contact materials where current is frequently interrupted. The object is usually to provide terminals which will not melt and weld together, as metal contacts sometimes do. Relays, contactors, and various control devices use buttons or studs of this type, making contact with moving parts of metal, usually brass or copper. Where high conductivity is required, copper-graphite or silver-graphite material is used. These are similar to metal-graphite brush material, giving non-sticking contacts with low contact drop and some degree of lubrication. Silver-graphite, although more expensive, gives lower contact drop after long service than copper-graphite. It is therefore used in low-energy circuits such as relays, where reliable operation, even after long periods of idleness, is important.

CARBON BRUSHES. The chief use of carbon in electrical manufacturing is for current collection. Carbon brushes form an important part of the electrical circuit in commutator machines, and many types have been developed to afford most satisfactory operation of motors and generators. Carbon brushes are used, rather than metal, in order to provide a resistance path for the short-circuit current which flows when a brush spans two or more commutator bars. The resistance offered must be high enough to prevent excessive coil currents, yet low enough so that the main load current led in or out of the brush will not cause excessive drop in total machine potential.

The essential features of brush manufacture and composition are as follows:

The three purest forms of carbon are diamond, petroleum coke, and lamp black. The last two ingredients are extensively used in the manufacture of carbon brushes and other carbon products.

Petroleum coke is the residue left on the bottom and sides of the still after the refining of crude oil. After all other products have been collected, this petroleum coke forms a shell of varying thickness and is dug out in chunks. This by-product, or green petroleum coke, is purchased in large quantities by all manufacturers of carbon.

Lamp black is made by the incomplete combustion of oil or gas, depending upon the type of black desired.

The first step in the process of manufacture is the driving out of all impurities or volatile matter from the green coke. This is done by subjecting the green product to an intense heat in calcining furnaces. The resulting product is pure carbon, or commonly termed, calcined coke. This calcined coke is then put through a grinding and sieving operation, similar to the operation of a wheat flour mill. All types of mills, including roller mills and pulverizers, are used. The resulting product is a fine, pure carbon flour, mainly 200 mesh and finer.

The carbon flour is then mixed with graphite, lamp black, and other ingredients, according to the formulas necessary to attain certain electrical and physical characteristics desired in standard grades of brushes. Graphite is added for lubricating purposes and to increase the current-carrying capacity of carbon brush material.

The highest-grade graphite brushes are made by transforming pure carbon brushes to graphite by subjecting the material to an intense heat in an electric furnace.

The method of making carbon graphite and graphite brushes is as follows:

1. Calcined petroleum coke, lamp black, graphite, or other flours are mixed with a pitch or other binder in steam-heated mixers.
2. After thorough mixing, material for molded brushes is permitted to cool and reground and pulverized, after which the fine powder mix is then molded under hydraulic pressure into plates.
3. The molded carbon graphite plates are then baked at various temperatures.
4. This completes the manufacturing process for carbon graphite and natural graphite plates from which brushes of these two classes are cut.
5. The carbon graphite plates from which electro-graphitic brushes are to be cut are given an additional high-temperature treatment in an electric furnace which removes all impurities and in addition changes some of the carbon into graphite.

Metal graphite grades are made by mixing fine mesh copper, lead, zinc, tin, or other materials with graphite. This material is mixed, molded, and baked in a manner similar to carbon graphite material.

Resin bonded brushes contain a certain amount of resin of high electrical resistance such as a condensation product resulting from the reaction of formaldehyde upon phenol. The brush structure is of a laminated texture which results in a cross electrical resistance approximately five times greater than the lengthwise electrical resistance. This has the effect of limiting circulating currents in the brush and providing better commutation.

The various formulas necessary to make grades of different electrical and physical

properties are governed by the characteristics of the electrical equipment for which the brushes are intended. The higher the metal content of brush material, the higher the current-carrying capacity of that material. Plain carbon graphite grades carry between 35 and 50 amp per sq in., whereas the highest content graphite grade carries about 70 amp per sq in. continuously. High metal content grades are rated at 125–150 amp per sq in. but will carry 450–500 amp per sq in. momentarily without undue heating.

The many grades of brushes on the market may be classified generally into five grades known as (1) carbon graphite, (2) electro-graphite, (3) natural graphite, (4) resin bonded, and (5) metal graphite.

Carbon Graphite. These are survivals of the original types and are used mostly on older-design machines where a cleaning action on the commutator is required. They are not suitable for high speeds or heavy currents.

Electro-graphite brushes have largely superseded the carbon graphite type. They have lower friction, higher current capacity, less ash, lower abrasive effect, and greater mechanical strength.

Natural Graphite brushes are an improvement over the carbon graphite type where abrasive action is beneficial but where low friction is required for higher-speed operation.

Resin Bonded brushes have a laminated structure whose distinctive characteristic is that the resistance across these laminations is from five to eight times the resistance parallel to the laminations. This is effective in reducing short-circuit current in the face of the brush. They are particularly suited to machines with high commutating voltage.

Metal Graphite brushes have replaced the early leaf copper types. They are used where high current capacity and low contact drop are important, as in electroplating generators or slip rings on a–c machines.

Navy Specifications. The following specification values of the U. S. Navy may be taken as illustrative of the range of properties existing in brushes in common use:

	Grade A*	Grade B*	Grade D*	Grade E*
Specific resistance at 30 deg cent, ohms per in.^{3}	0.00176–0.0021	0.0015–0.0019	0.0006–0.0012	0.000005–0.000025
Specific resistance at 250 deg cent, ohms per in.^{3}	0.0013–0.0017	0.0011–0.0015	0.0004–0.0010	....
Contact drop, volts at rated current	1.5 min 3.2 max	1.8 min 3.0 max	1.6 min 3.0 max	low
Coefficient of friction (no current)	0.50 max	0.55 max	0.60 max	0.40 max
Coefficient of friction (carrying current)	0.35 max	0.40 max	0.45 max	....
Transverse strength, lb per in.^{2}	2100 min	3000 min	1000 min	2500 min

INSULATING MATERIALS

8. CLASSIFICATION

Insulation materials may be classified according to:

a. Thermal limits (A.I.E.E. operating temperature classes).
b. Physical state (solid, liquid, etc.).
c. Quality [good dielectric (e.g., mica) or poor dielectric (e.g., asbestos)].

The Thermal Classification as defined in A.I.E.E. Standards is as follows:

Class	Description of Material
O	Class O insulation consists of cotton, silk, paper, and similar organic materials when neither impregnated * nor immersed in oil.
A	Class A insulation consists of cotton, silk, paper, and similar organic materials when impregnated * or immersed in oil; also enamel as applied to conductors.
B	Class B insulation consists of inorganic materials such as mica and asbestos in built-up form combined with binding substances. If Class A material is used in small quantities in conjunction, for structural purposes only, the combined material may be considered as Class B, provided that the electrical and mechanical properties of the insulated winding are not impaired by the application of the temperature permitted for Class B material. (The word "impair" is here used in the sense of causing any change which could disqualify the insulating material for continuous service.)
C	Class C insulation consists of inorganic materials such as pure mica, porcelain, and quartz.

Physical Classification. To give an idea of the variety of types of materials used as insulators, a list of physical classifications is herewith shown.

Solids
- Natural (marble, slate, asbestos, quartz, mica, lava, soapstone).
- Vitreous (glass, porcelain).
- Fibrous, organic (cotton, silk, linen, threads, and fabrics, paper, wood).
- Rubber materials and substitutes (rubber, gutta percha, Duprene, Thiokol).

Plastics
- Synthetic resins (phenolic, urea, resorcinol, vinyl, casein, etc., used as impregnation of fibrous insulation or as molded composition and laminated sheet).
- Waxes (natural and synthetic, beeswax, halowax, paraffin).
- Gums (natural gums, asphalt, shellac, copal).

Liquids
- Natural oils (linseed, tung, castor).
- Mineral oil (transformer and switch).
- Varnishes.
- Solvents (benzine, alcohol, naphtha, toluol, etc.).

Gases
- Air
- CO_2
- N_2
- H_2

9. DISCUSSION OF PROPERTIES

DIELECTRIC STRENGTH. The electric strength of a dielectric material is the maximum potential gradient that unit thickness of the material can withstand without rupture. With solids, breakdown is frequently termed puncture. With thin sheet

* Impregnated cotton, paper, or silk: An insulation is considered to be "impregnated" when a suitable substance replaces the air between its fibers, even if this substance does not completely fill the spaces between the insulated conductors. The impregnating substance, in order to be considered suitable, must have good insulating properties, must entirely cover the fibers and render them adherent to each other and to the conductor, must not produce interstices within itself as a consequence of evaporation of the solvent or through any other cause, must not flow during the operation of the machine at full working load or at the temperature limit specified, and must not unduly deteriorate under prolonged action of heat.

insulation the dielectric strength is commonly expressed in volts per unit thickness, as volts per mil.

The breakdown or puncture voltage of any sample is influenced by a number of factors—size and shape of electrodes, the frequency and wave shape of the applied voltage, time of voltage application, temperature, moisture content. The methods of test published by Am. Soc. for Testing Materials are generally recognized as standard. It is essential that the conditions of test should be known in comparing different materials.

Table 1 illustrates the effect of the thickness of the test specimen upon the dielectric strength of porcelain. The effect may be greater or less for other insulating materials. It is obvious, however, that a standard thickness of the test specimen should be adopted in order to obtain comparable values of dielectric strength of the various insulations.

Table 1. Dielectric Strength of Porcelain for Different Thicknesses of Test Specimen

(Peek: Dielectric Phenomena in High Voltage Engineering)

Total Thickness, mm	Kv per mm	Total Thickness, mm	Kv per mm
0.5	16.0	5.0	11.0
1.0	14.5	10.0	9.6
2.0	12.2	15.0	9.2

Effect of Time of Voltage Application. Time is an important factor in dielectric breakdown. This is due to effect of heating, cumulative products of ionization, or lining up of particles of low dielectric strength. The following data, taken with rod electrodes (spherical ends) at large spacings in transformer oil, show that a voltage much lower than the short-time breakdown value of a given dielectric will cause breakdown if applied for a long time. Instantaneous values can therefore not safely be used in design unless a generous factor of safety is allowed.

Table 2. Variation of Dielectric Strength of Oil with Time of Applied Voltage

1/4-in. Diameter Spherical Electrodes

Spacing, inches	Instantaneous Breakdown, kv	Voltage for Breakdown at 1 Min, kv	Voltage for Breakdown at 3 min, kv	Voltage for Breakdown at 10 Min, kv
2	295	180	125	90
4	320	230	155	145
8	345	280	225	225
16	420	375	365	365

Effect of Temperature. Table 3 illustrates the effect of time of applied voltage on a solid dielectric. It demonstrates also the reduction of dielectric strength with increase in temperature. Care must be taken in applying data on commercial insulating materials. The breakdown values, resistivity, and other properties are quite likely to be greatly reduced at operating temperatures of electrical apparatus.

Table 3. Variation of Dielectric Strength with the Time of Applied Voltage

(Peek: Dielectric Phenomena in High Voltage Engineering)

Material	Thickness, mm	Time to Puncture, min	25 deg cent kv per mm	100 deg cent kv per mm

.50	...	116	55

SURFACE LEAKAGE is due to a film of moisture on the surface of the insulation. This moisture may contain soluble salts and condensed gases, such as ammonia, and carbon dioxide from the air. This film may indeed be very thin; for example, on cleaned quartz glass, it has been found to be from 3 to 6 $\times$ 10^{-6} mm. Waxy materials have no surface film because the moisture condensed on the surface tends to draw into drops instead of spreading over the surface. Surface resistivity according to Curtis is independent of voltage and also temperature, the relative humidity being constant. The temperature range which he investigated was 25 to 30 deg cent with relative humidity at 25 per cent.

Surface resistivity of most insulating materials decreases upon exposure to sunlight or ultra-violet light. The results obtained by Curtis indicate that a few hours of exposure to ultra-violet light will produce the same or sometimes a greater effect than would be produced in years by sunlight.

Surface resistivity is defined as the resistance between two opposite edges of a surface film, 1 cm square. The values in Table 4 are those obtained by Curtis at temperatures from 25 to 29 deg cent and are given for 30 and 90 per cent relative humidity. The test voltage was 200 volts.

On high voltages, apparent surface leakage should be distinguished from actual surface leakage. The surface moisture film under high voltage is soon dispelled by the heat generated with the leakage current. Then a new leakage film is produced by the oxidation of the insulation with ozone generated at the surface due to corona formed by local ionization of the surrounding air. If the surface of the insulation is covered with an oil such as blown linseed oil prior to the application of the voltage the oxidized film can be greatly reduced, and the arcover or flashover voltage will be increased. Even though all the actual surface leakage were removed, the flashover voltage would still be limited because of the apparent surface leakage, which, for a given leakage distance, depends upon the position and shape of the electrodes, relative specific inductive capacities of air, and the insulation and the shape of the insulation (contour of the surface). If no surface leakage at all existed the flashover voltage would then be the breakdown voltage of the air between the electrodes. (Adapted from Peek, Dielectric Phenomena in High Voltage Engineering).

In high-voltage designs surface breakdown must be prevented by providing sufficient creepage distance. The characteristics of sheet insulating materials such as mica, laminated Bakelite, fullerboard, etc., have been investigated. As an example, Fig. 1 shows the surface breakdown voltage for mica plate in air. The high voltage electrode was a 2-in. square block of brass, $^1/_2$ in. thick, placed on the mica sheet at given distances from the edge. The mica was placed on a large sheet of metal, which formed the grounded electrode. Failure was thus over the surface and across the thickness of mica sheet to the metal plate.

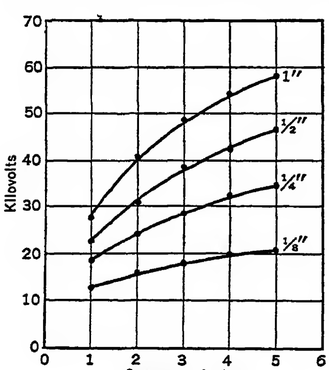

FIG. 1. Surface Creepage. Mica plate 1/8″ to 1″ thick

VOLUME RESISTIVITY of insulating materials in general follows Ohm's law. The only exceptions of any consequence are a few vegetable oils, as for example castor oil, in which the resistance decreases with increase in the applied voltage. The volume resistivity varies with the amount of moisture present and with the temperature. In Shrader's work on the effect of moisture, he found, for example, an insulating material, which is generally considered non-hygroscopic, had a volume resistivity of 26 $\times$ 10^{10} ohm-cm ordinarily, but after being heated in vacuum, had a resistivity of 8 $\times$ 10^{14} ohm-cm, or 3000 times as great. As to the effect

of temperature, Curtis found that in 53 of the insulations which he investigated, the ratio of the resistivity at 20 deg cent to that at 30 deg cent varied from 1 to 5.3.

The values given in Table 4 are for room temperature at ordinary atmospheric humidity. The unit used is the resistance to the current flowing through the material between two opposite faces of a centimeter cube, no surface leakage being present.

Table 4. Electrical Properties of Insulating Materials

Material	Dielectric Strength		Resistivity			SIC
	Specimen thickness, mm	Kv per mm (a)	Volume ohm-cm	Surface (b) Ohms, 30%	Surface (b) Ohms, 90%	Air Unity

(a) To obtain volts per mil multiply kilovolts per millimeter by 25.4.
(b) At 30 per cent and 90 per cent relative humidity.

DIELECTRIC LOSS is due to the following causes:

With either direct or alternating current.

1. Ionization of occluded gases.
2. I^2R losses due to leakage current.

With alternating current only.

3. Oscillatory movement of particles of higher or lower specific capacity than the surrounding medium, due to the charges induced on them being alternately attracted and repelled by the electrodes.
4. I^2R losses due to displacement current.

Generally, dielectric loss varies as the square of the voltage up to a certain dielectric stress at which the loss begins to increase faster than the square of the voltage. The increase occurs when the occluded gases or other particles of low specific inductive capacity begin to ionize. This has the effect of greatly increasing the dielectric stress on the particles of high specific capacity which soon rupture. Dielectric loss therefore has a

bearing upon the dielectric strength of insulations especially when the voltage is applied indefinitely.

Table 5 gives dielectric loss of varnished cloth and oil-treated paper.

Table 5. Dielectric Losses

(Peek: Dielectric Phenomena in High Voltage Engineering)

(Effective Sine Wave 60 Cycles)

Total Thickness, mm	Insulation	No. of Layers	Temp., deg cent	Volts per mm	Watts per cc
4.0	Varnished cloth	15	25	4,000	0.005
				6,000	0.015
				8,000	0.035
				10,000	0.060
				12,000	0.090
4.0	Varnished cloth	15	90	4,000	0.025
				6,000	0.075
				8,000	0.150
				10,000	0.240
				12,000	0.350
2.5	Oil-treated paper	30	25	10,000	0.040
				14,000	0.070
2.5	Oil-treated paper	30	60	10,000	0.043
				14,000	0.080
2.5	Oil-treated paper	30	90	10,000	0.050
				14,000	0.100
2.5	Oil-treated paper	30	120	10,000	0.067
				14,000	0.138

These losses may be lower or very much higher, depending upon the condition of the insulation.

The power factor of insulation is the ratio of the power dissipated in it (i.e., the dielectric loss) to the product of volts across it and amperes in the circuit.

Dielectric loss is of great importance in some high-voltage devices, such as cables and condenser-type terminals. It is also a determining factor in the choice and use of materials for capacitors. High losses lead to heating of the dielectric and low efficiency. If too high, losses cause heating resulting in still higher losses, and so on cumulatively to failure of the dielectric.

The variation of power factor and specific inductive capacity with temperature on cable and cloth tape are shown in Table 6. It is apparent that operating temperatures, whether from ambient conditions or internal losses, should be kept low.

Table 6. Power Factor and Specific Inductive Capacity (SIC)

Temp. °C	Tan Tape		Black Tape		Cable	
	Per Cent Power Factor	SIC	Per Cent Power Factor	SIC	Per Cent Power Factor: Single Cond.	Per Cent Power Factor: Multiple Cond.
20	3.4	4.5	3.0	3.9	7	10
40	4.3	5.0	3.0	4.2	7	10
60	5.4	5.5	3.2	4.5	10	15
80	9.2	6.0	4.8	4.6	16	25
90	14.5	6.4	6.5	4.7	—	—

POWER FACTOR TEST OF TREATED MATERIAL (PAPER AND COTTON). Measurements of power factor are usually made at two temperatures, 25° C. and 80° C. and at two voltage gradients, 30 and 100 volts per mil. The Schering bridge, or a more recent modification, the Atkinson bridge, is used to obtain the values. Great care must be taken in preparation of the sample to insure reliable results. If entrapped air or moisture is present, a proper test is impossible. One procedure which is tedious but reliable is to prepare a sample of tape wrapped on a metal tube about 2″ in diameter and about 12″ in effective length. To eliminate air, hot insulating oil is applied to the tube and to each carefully wrapped layer. Over the outside a foil electrode and guard rings are placed. A successful method of testing flat samples of tape (approx. 1″ × 6″) has

been developed and standardization of procedure is being completed by A.S.T.M. To insure consistent results, the sample is dried at least three hours at 105° C. and many authorities follow this with sixteen hours of vacuum drying. A considerable pressure of electrodes is desirable, such as 10 lbs. per sq. in.

IMPULSE CHARACTERISTICS. The behavior of insulating materials when subjected to steep wave front surges is of great importance in all apparatus used in the transmission and distribution of electric power. Voltage surges may be due to lightning or to switching disturbances and may vary greatly in steepness, maximum voltage, decay of wave, and may be of either polarity. The various insulating parts of a system should be

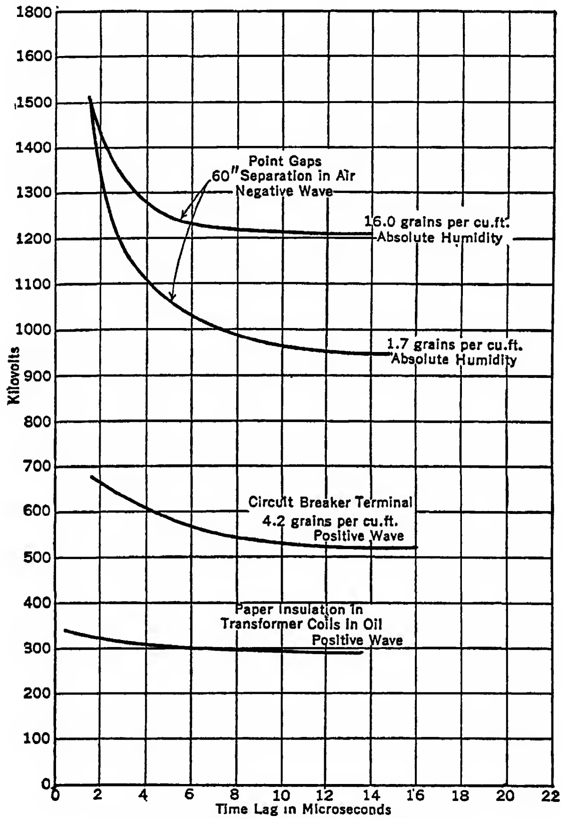

FIG. 2. Time Lag Curves (1.5 × 40 wave)

coordinated so that selective protection is obtained. For example, the line insulators should flash over and give relief if necessary before the circuit breaker terminals, and the terminals should break down before the transformer insulation. Only in recent years have laboratory tests on materials and apparatus been coordinated sufficiently to permit comparison of different products and to evaluate the protection installed on any system. Two types of waves are in general use, the 1 × 5 and the 1.5 × 40, tentatively agreed upon by A.I.E.E. subcommittees. The first figure is the time in microseconds to the crest of the wave and the second figure is the time in microseconds from zero to half crest value on the tail of the wave.

In the literature various investigators have given results on impulse tests of various materials but they are not of great use because of the former lack of standardization of test waves and procedure. In surge breakdown of insulation, time is a major factor. For example, if a wave of which the crest voltage is slightly above the 60 cycle crest

breakdown is applied, breakdown may occur perhaps 15 microseconds after the start. If a wave with a crest voltage 50% higher is applied, breakdown will occur more quickly, perhaps in 2 microseconds. Such tests over a range of voltages give data for time-lag curves which are of great use in coordinating the insulation of various structures. Time lag curves are of hyperbolic shape in general, approaching the 60 cycle crest value as an asymptote (see Fig. 2). The degree of curvature varies with the material. In the case of air the curve is very steep. The crest value of 1.5 × 40 waves which will cause breakdown of air in 2 microseconds may be 1 1/2 to 2 times the crest value of the 1.5 × 40 wave which will produce breakdown in 15 microseconds. With solids such as terminals and transformer coil insulation the shape is much flatter, there being less difference in voltage for breakdown for differences in time chosen.

10. SOLID INSULATING MATERIALS

Insulating materials are often described in general terms without specific data. A material is said to be "heat proof," which may mean that it will not deteriorate when used continuously at some temperature within the range of 30 to 250 deg cent. Dielectric strength is sometimes quoted without reference to the thickness of the test specimen. If the test has been made on a very thin specimen, the dielectric strength obtained will be misleading to those who are not aware of the law of the increase of dielectric strength with the decrease of the thickness of the test specimen. Claims may be made that an insulating material is insoluble in certain solvents and is weatherproof. Such claims are not absolute. They are only general and refer to ordinary conditions found in the use of insulations. If the working conditions are unusual and severe, specific information should be obtained on the appropriateness of the insulation under consideration.

The more important types of insulation are described in the following pages.

Natural

ASBESTOS is a mineral consisting chiefly of silica, magnesia, lime, alumina, water, and oxide of iron. The structure is of innumerable fibers the ultimate fiber of which is thought to be a single row of the molecular structure of the crystal. The fibers are exceedingly smooth and glossy and have very little friction to hold them together when they are spun into a yarn, this resulting in a low tensile strength. This difficulty, however, has been partly overcome so that now threads are made which have fair tensile strength. The more important varieties of asbestos are amianthus and amphibole and are used in the form of asbestos paper, cardboard, yarn, cloth, tape, and as a filler in molding mixtures.

Asbestos contains small particles of iron oxide or grit which cannot be entirely removed and affect to a slight degree its insulating qualities. It is hygroscopic and should therefore not be used on high voltage, in general not over 3300 volts. It is unaffected by oils, acids, and alkalies and withstands very high temperatures. Above 500 deg cent it loses its mechanical strength, and it melts at about 1300 deg cent. It has an extensive use as a heat insulator.

LAVA is a mineral talc, machined in its natural condition and then baked at a temperature of 1100 deg cent to a condition of extreme hardness. It is then unaffected by any subsequent temperature short of its baking temperature. It is slowly attacked by hydrochloric acid but is not affected by other acids or alkalies.

MARBLE is the name given to any limestone which is sufficiently compact to admit of a polish. Pure marble is white, but the presence of iron oxide or other impurities gives it different colors. It is used principally for switchboard work and should not contain metallic veins, which reduce its insulating qualities. If used on circuits of 1000 volts or more, it should be saturated with an insulating varnish and baked. It shows oil spots, and for that reason it is sometimes stained black and given a so-called marine finish. Very little marble is now used except to match old installations.

SLATE is any rock having a fissile structure, the common variety being composed principally of silica, alumina, and oxides of iron. It is hygroscopic. It is often permeated by metallic veins, making it unfit for use unless the electrical connections are insulated by bushings. It is useful for switchboard and switch-base work owing to its desirable mechanical and fireproof qualities. Its dielectric strength decreases rapidly as the temperature increases, and at a high temperature slate becomes a conductor. When a high voltage is impressed upon a piece of slate for some time, the slate usually is not punctured but, owing to the consequent rise in temperature, the slate acts as a short circuit to the impressed voltage. The breakdown is thus only apparent as the specimens regain their dielectric properties after cooling.

Slate from some localities is a better insulator than that from others. Purple slate from Vermont and vicinity is considered superior to black slate from Pennsylvania. The use of slate for electrical purposes is rapidly declining.

QUARTZ a form of silica, naturally formed into hexagonal crystals, has a density of about 2.7. It may be fused and cast into usable shapes and is sometimes used as a ceramic type of insulation for high temperatures.

SOAPSTONE, a form of talc or steatite, is gray in color and feels smooth and soapy. It is very easily machined and is sometimes used as an insulator and structural part where resistance to heat and chemicals is desired. It is weak mechanically and hygroscopic.

MICA is an anhydrous silicate of aluminum and potash or sodium. It crystallizes in a laminated mass, some grades of which may be subdivided down to a thickness of 0.0008 mm. The ultimate thickness of cleavage layers is unknown and may be finally but one layer of the molecular structure. It is useful as an insulator because of its high insulating qualities and its ability to withstand high temperatures. Owing to its impurity, lack of flexibility, and excessive surface leakage in the natural state, the laminae are separated and sorted into various grades of purity and are then cemented together to form plate or flexible reconstructed mica of any thickness or purity.

Two kinds of mica are in common use—muscovite (white mica), usually obtained from India; and phlogopite (amber mica), from Madagascar.

Mica can be built into various useful forms, including plate, flexible mica, tape, coil wrappers, and tubing. Mica is combined with thin paper or cloth as a backing when made into tape or wrappers. The bond is frequently shellac although asphalts, synthetic resins, and other materials are preferred for special purposes. White mica is hard and is used in building segment mica for undercut commutators. The maximum safe temperature for white mica is 500 deg cent.

Amber mica is softer and is used in mica plate for flush commutators. It is also used in making plate for heating-appliance insulation. It will withstand temperatures up to 800 deg cent.

Flexible mica or molding mica may be made for hot or cold molding. White mica is generally used with a bond which is plastic at the molding temperature. Shellac bond may be flexibilized with castor oil.

Sheet insulation is made with mica and some other insulation such as fishpaper, rope paper, or Kraft paper for special purposes.

Solid-vitreous

GLASS. Glass is essentially a mixture of silicates of sodium, potassium, calcium, or barium. A given specimen may contain one or more of these silicates, the composition being chosen so as to give the desired properties. Other metallic oxides are often added, and if a low-expansion, heat-resisting glass is desired, boron trioxide is used, to make the borosilicate glass.

At normal temperatures glass is a good insulator but at red heat is a fair conductor. It resists most chemicals except hydrofluoric acid. Most glass is brittle and weak on heat shock. Newer glasses of the borosilicate type (Pyrex) have lower coefficients of expansion and do not shatter with wide temperature changes. Successful line insulators have been placed on the market, competing with porcelain.

PORCELAIN. Porcelain is distinguished from other forms of earthenware by a vitrified and non-porous structure. It is composed of china clay, ball clay, flint, and feldspar. China clay, sometimes called kaolin, is slightly plastic whereas ball clay is very tough and plastic. By a proper combination of the two the desired plasticity is obtained. Flint is in the form of pure sand or quartz ground so finely as to be entirely free from any gritty feeling. Feldspar is a natural rock and is ground as fine as the flint. These four ingredients are mixed in proper proportions and passed through the manufacturing processes, which require very skilful care and experience upon which depends the quality of the product.

Insulators are made by a wet process and are non-porous, which is necessary for high-voltage use. The glaze is provided to protect the porcelain from dust and deterioration in the weather and should have the same temperature coefficient of expansion as the porcelain.

In the wet process the ingredients are thoroughly ground in a ball mill and then mixed with water to a consistency about the same as that of paint. After several hours of stirring (blunging) this liquid (slip) is pumped through a filter press where the water is extracted and press cakes left. These are stacked in bins for use, being kept moist. Thorough mixing of the press cake material is accomplished by a screw type of mixer called a pug mill. The wet clay is extruded in cylindrical form and sections cut off for forming into

insulators or other parts. Forming is usually done either by hot pressing the plastic clay soon after it leaves the pug mill, or by turning operations performed after the clay has partially dried. Wet-process material may also be cast into plaster of paris molds, a special liquid body being prepared for this purpose. Porcelain is fired at temperatures ranging from 1250 to 1300 deg cent for several days.

Such articles as knobs, cleats, and lamp sockets are made by a dry process. Dry-process body is a moist powder when molded. Such porcelain is porous and not usually suitable for high-voltage outdoor applications. It is of value because of the accuracy with which intricate pieces can be molded and is suitable for indoor or low-voltage purposes.

The mechanical strength depends upon the flint content, the heat resistance upon the clay, and the dielectric strength upon the feldspar which unfortunately also adds brittleness. In a special type of porcelain for spark plugs, magnesia is used which adds mechanical strength at high temperatures. Porcelain, because of its low tensile strength, should be used under a compressive strain. It is comparatively inexpensive, chemically inert, and not sensitive to changes of temperature. The fracture of good porcelain is conchoidal, fine grained, white and bright.

Fibrous Organic

COTTON. Cotton occurs in many forms as an insulator, such as cloth, tape, and yarn. These products serve as mechanical supports or separators of conductors and are usually impregnated with an insulating liquid or compound. The insulating value of cotton is considered only equivalent to the same thickness of air, reliance being placed usually on the impregnation for dielectric strength and moisture proofing. Cloth is used in making varnished "cambric" of various types. Tape is used largely in insulating coils of all types, and yarn in covering wires or insulating layers of enameled wire in "universal" wound magnet coils.

SILK is not frequently used as an insulator, except where space is an important factor. It is sometimes used as a varnished fabric or as wire covering for appearance and because it can easily be obtained thinner than cotton materials. The cost is higher, however. Its insulating properties are approximately the same as those of cotton.

LINEN thread or twine is used for fastening the coils of rotating machines because of its high unit strength.

PAPER. A great variety of papers are used for insulation, usually impregnated the same as cotton. Paper insulation occurs as sheets, treated either before or after application for layer insulation; as tape for insulating conductors; or in combination with mica, asbestos, or cloth for various applications. Paper is principally of rag, wood fiber, or vegetable fiber origin.

INSULATING PAPERS. The principal papers used in electrical apparatus are described below.

Absorbent Papers of 100 per cent purified sulfite wood pulp are used in making laminated phenolic products. The paper has a soft fiber, thoroughly cleaned of natural resin, and it takes the impregnating phenolic varnishes readily. A plate with a high ratio of impregnation weight to paper weight can be made with absorbent papers. A common thickness is 0.010 in.

Another type of absorbent paper is made from 100 per cent cotton rag stock to be used in filter presses employed in purifying insulating oils. It is very porous, to absorb water readily, and yet let oil through. The thickness of sheet is approximately 0.025 in.

Asbestos Paper is not all asbestos fiber, the usual grades containing not more than 80 per cent asbestos and the remainder sulfite wood pulp fibers. Thin papers from 0.005 to 0.010 in. are used in insulating heavy copper used in field coils and in tape form as a covering for wire. Certain grades of heat-resisting laminated phenolic plate are made of asbestos paper impregnated with materials like Bakelite. Asbestos papers are not high-grade insulators owing to conducting particles and moisture absorption.

Rag Base Papers. (*a*) Tough insulating papers used where resistance to mechanical damage, as in motor and generator slots, is important, are manufactured from 100 per cent cotton rags. Most of them are identified by trade names, such as Duro, Capacio, and Armco papers.

(*b*) Fish paper is a special type of rag paper made entirely from old cotton rags. The paper during manufacture is treated with zinc chloride which partially dissolves the cellulose. A paper is obtained without a definite fiber structure. It is hard, tough in both directions, and does not dislaminate. Fish paper may be obtained in thicknesses from 0.007 to 0.056 in. and is used for slot insulation, for layer insulation of coils, and as switch barriers. Paraffin impregnation or varnish treatments are frequently used to overcome the inherent hygroscopic property of fish paper.

Fullerboard (or Pressboard). (*a*) Rag fullerboard is composed of 75 per cent rag stock and 25 per cent sulfate wood pulp. It is made on a cylinder machine, cut off, dried, and pressed in sheets. It may be obtained in thickness from 0.007 to 1/2 in. and in sheets as large as 84 by 120 in. Fullerboard is particularly adapted for oil impregnation and is extensively used in transformer construction for barriers, coil sides, and washers. It may be formed into angles and channels. Shrinkage and distortion are low.

(*b*) Kraft fullerboard made of 100 per cent sulfate wood pulp in the same general manner as rag fullerboard is a cheaper type of material and is valuable for many applications for which rag fullerboard was once employed. It is used for barriers, coil spacers, washers, etc., for electrical machinery. It has much greater shrinkage and warping tendencies than rag material. Forming is not as readily done. These limitations result in the continued use of both rag and Kraft types. Varnish treatment is frequently applied when fullerboard is to be used in air.

(*c*) A similar material in thin papers with a highly calendered surface is called express paper. It is used making varnish-treated papers where only a surface coating and not impregnation is desired.

(*d*) A compromise material containing 60 per cent rag and 40 per cent woodpulp has been developed which combines practically all the stability and toughness of rag fullerboard with the cheapness of Kraft fullerboard.

Kraft Papers contain 100 per cent sulfate wood pulp and may be obtained in a range of thickness from 0.0005 in. to fullerboard thicknesses. They are brown in color, are readily impregnated, and are among the most useful electrical papers. Many grades of laminated resin (phenolic or other) plate and tubing are made with Kraft paper. It is also used, shellac coated, in making rolled paper bushings and terminals. Very thin Kraft tissue (0.0005 in.) is now used in capacitors largely replacing linen and cotton tissue formerly employed.

Linen. So called linen papers are part cotton, sometimes as much as 60 per cent. They are strong and tough and have been used in very thin grades for condenser (capacitor) insulation. The use of linen in all forms (cloth, paper, and twine) is not nearly so extensive as it once was. Cheaper satisfactory substitutes have been found.

Japanese Paper is imported from Japan and is made of mulberry pulp fiber. The particular feature of this fiber is the great length, giving good strength, although the paper looks frail and not dense. Tissue (0.001 in.) finds use as a backing for mica tape and as wire insulation. It is not suitable for capacitors because of small holes and lack of uniform structure.

Rope Paper may be manufactured either from manila hemp fiber or from old manila hemp rope. It is very strong, resisting tear better than cotton paper. It is frequently impregnated with varnish and used in combination insulations such as mica and rope paper. When made from old rope, the paper frequently contains metal particles. For this reason, other papers are usually preferred for high-insulation duty. Rope paper can be folded and crimped. It is thus used in holding wires in some types of coils where flanges are omitted.

CELLOPHANE is a pure cellulose product made from wood pulp by chemical treatment. It is transparent. It is obtainable in sheet, tubing, and tape forms. The dielectric strength and specific inductive capacity are high (see table), and inflammability is no greater than that of paper. Because of its purity it has much promise as an insulator and has been used as wire insulation and coil taping. Some varieties named "flameproof" and "moisture proof" are now available. Moisture proofing is accomplished by a lacquer coating. Some grades of cellophane are flexibilized with the addition of glycerin.

CELLULOSE ACETATE is obtained by acetic anhydride treatment of cotton fiber or purified wood pulp. It has high dielectric properties and uniformity of characteristics. It can be obtained in the same forms as cellophane and is used for similar applications. It is comparable in inflammability to paper. It is not as hygroscopic as regular cellophane.

VARNISH-TREATED CLOTH. Varnished cloth, usually muslin, is widely used as an insulating material. It is sometimes known as varnished cambric or empire cloth. It enters the manufacture of cloth-insulated cables, is used as coil wrappings, especially on end turns of rotating machines, and in combination with paper as a lining for coil slots. Coil terminals on large transformers are taped with varnished cloth.

The fabric is most commonly an unbleached cotton cloth of 60 to 64 threads per inch and in various thickness from 0.005 to 0.015 in. Treatment consists of impregnating and coating with varnish. This is done in a tower through which the cloth passes continuously. It passes through successive varnish baths and is dried by heat between dips. When it emerges it has had from two to four dips and bakes. The varnishes generally used are two of the natural oil types, tan cloth varnish or black. The tan is somewhat more oilproof and less moisture proof than the black. The black is usually asphaltic but

can be made satisfactorily oilproof. The dielectric properties of black cloth are generally superior to those of tan. Black cloth finds a large use in cable manufacture. For this purpose it must possess low power factor and losses. The surface coat of varnish may be made relatively hard and smooth; tacky so that, in taping, successive layers will stick together; or greasy so that layers of tape on irregular forms will slip into place easily.

Some properties of insulating fabrics and papers are shown in the following table:

Table 7. Insulating Fabrics and Papers

Material	Thickness	Breakdown Volts	
		1 Layer	Per Mil
Treated Cloths			
Asbestos cloth, varnished	0.047	3,780	80
Asbestos tape, varnished	.037	3,145	85
Cambric tape, varnished black, bias	.010	13,640	1364
Cambric tape, varnished tan, bias	.010	11,515	1151

Rope cement paper, shellac 2 sides	.016	8,850	553

Cloths and papers tested flat between 2-in. circular electrodes. Average of 10 breaks. (60 cycles.) Tapes tested by wrapping on 1-in. diameter rod in half lapped layers. Average of 10 breaks. (60 cycles.)

The effect of pull on the dielectric strength and stretch of tape is of importance. Tape must be capable of conforming to irregular forms and must therefore stretch to an extent, but must be neither too stiff nor too weak. The curve of Fig. 3 shows satisfactory performance of a black tape.

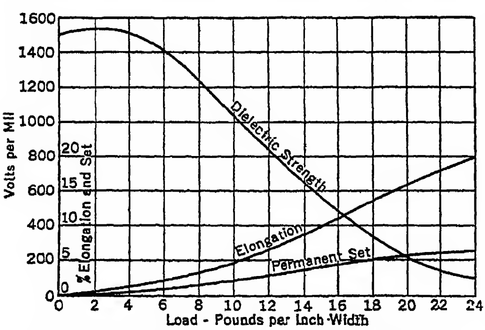

Fig. 3. Effect of Stretch on Black Varnished Tape

WOOD. Dry wood is a good dielectric and possesses the advantages of low cost, light weight, and strength with toughness. Probably the most frequently used woods are maple and hickory. White pine is a good insulator, especially when oil treated, but is not strong. Wood is generally treated with oil (linseed, tung, or transformer) or some wax or gum to fill the pores and keep out moisture. For use in air it is frequently given a finish of baking varnish.

FIBER is pure cotton cellulose chemically treated to form a hard, bone-like material. It is known by various trade names such as Fiber, Vulcanized Fiber, Hard Fiber, Horn Fiber. Fiber of best quality has its origin in old rags, because the natural oil of the virgin cotton fiber is deleterious and cannot be easily removed by chemical processes.

This oil is removed in the wearing and washing of the garment. All dirt and grit must be removed from the rags. The quality also depends on the softness of the rags.

Vulcanized Fiber sheets are made by passing cotton rag paper through a strong acid or zinc chloride bath and rolling it up on a large drum where each layer of paper sticks to the layer beneath it. When the proper thickness is obtained the acid soaked material is cut from the drum and cut in half forming two sheets of raw fiber. These sheets are put through a soaking process in large wooden tubs, each subsequent tub containing a weaker solution, the last tub containing pure water. (Catalog of the Continental Fiber Co.)

The soaking process requires from one week to one year, depending on the thickness of the sheet. A very small amount of acid or chloride will remain in spite of all the soaking. The sheets are air dried and seasoned at a constant temperature. During the drying, they warp and shrink to one-half the original thickness. They are flattened in a steam-heated hydraulic press and then calendered to exact thickness.

According to Almy the mechanical and physical properties of fiber vary between wide limits according to the manipulation of the chemical treatment and the varying quality of the original paper or rags. A fiber for a particular use should therefore be selected with great care.

Fiber is not waterproof. Dilute acids and alkalies cause no other effects than water, but concentrated acids cause disintegration. Organic solvents and oils have no effect whatever. At a sustained temperature of 80 to 100 deg cent, it loses its water of condition and becomes brittle, and it chars in a short period of time at 200 deg cent.

Fiber is widely used because of its strength, toughness, and comparatively high insulating values when dry. It is easily formed and machined. It resists the action of arcs on the surface to a great degree. The following specification properties of fiber have been taken from the N.E.M.A. Standards, 1931.

Table 8. N.E.M.A. Specifications for Hard Fiber

Minimum Tensile Strength at 20 Deg Cent

(Pounds per Square Inch)

Thickness, in.	Bone		Commercial Grades	
	Crosswise	Lengthwise	Crosswise	Lengthwise
Up to 1/8 incl.	6500	8500	6000	8000
1/8 to 1/2	6000	8000	5500	7500
Over 1/2	....	....	5500	7000

Minimum Transverse Strength

(Pounds per Square Inch)

Commercial Grade	Crosswise	Lengthwise
Load applied on	Face or edge	Face or edge
1/2 in. thick and over	11,000	13,000

Adopted Standard 9/24/1926.

Minimum Dielectric Strength

All Grades, in.	Volts per Mil
Up to 1/16 incl.	175
Over 1/16 to 1/8 incl.	150
Over 1/8 to 3/8 incl.	100
Over 3/8 to 1/2 incl.	50
Over 1/2 at least (total volts)	25,000

Minimum Dielectric Strength for Thin-weight Fiber and Fish Paper

Thickness, in.	Volts per Mil
0.004 to 0.005 incl.	200
Over 0.005 to 0.015 incl.	300
Over 0.015 to 0.040 incl.	250

Adopted Standard 10/22/1930.

MAXIMUM WATER ABSORPTION

Per Cent Change in Weight After 1 Hour Immersion

Thickness, in.	Bone	Commercial
Up to 1/16 incl	45.0	65.0
Over 1/16 to 1/8	20.0	35.0

Rubber Materials

RUBBER. (See also Gutta-percha; Wires and Cables.) Rubber is derived from the milky secretion or latex of certain tropical trees, creepers, and shrubs found chiefly in America, Africa, Ceylon, and Malacca. When these plants are tapped, a thick milky looking fluid or latex exudes from them. This latex is composed of very minute oil-like refractive globules, varying in size, which are in a state of rapid Brownian movement in a clear transparent liquid, called the serum. Besides these *caoutchouc* globules, or rubber-gum proper, the serum contains resins, protein, enzymes, and various organic and inorganic compounds. Rubber or India rubber is the dried-up or coagulated latex. The best rubber is from a tree known as the *Hevea brasiliensis*, and is known as *Hevea* rubber. It grows wild in Brazil and is cultivated in Ceylon and the Malay Peninsula. In Brazil coagulation is effected principally by dry heat or smoking. A wooden paddle is dipped in the latex and held over a smoky fire until the latex has coagulated. This process is repeated until the caoutchouc layers have become sufficiently thick, when the lump of raw rubber is cut off, dried for several days, and dispatched usually as "fine Para biscuits" to a trading center. The plantation rubber is coagulated in sheets by means of acetic acid. If subsequently smoked it is known as "smoked sheets." Para entrefine, Negro Heads, and Sernamby are usually prepared from fine Para rubber which adheres to the tree during tapping or to the vessels containing the latex.

A relatively recent development is the shipping of the preserved latex in the liquid form. This may then be treated to precipitate the rubber particles, or used directly for impregnation of cords or fabrics.

Acetone Extract. In addition to the pure rubber gum, washed rubber contains resins and proteins which are soluble in acetone and are therefore often known as "acetone extract."

Impurities in Wild Rubber. Wild rubber contains, in addition to the caoutchouc, a number of foreign substances, such as sand and bark, which can be removed by mechanical washing, followed by drying.

Manufacture of Rubber Insulation. The rubber is milled passed between heavy rollers and broken down to a plastic mass. It is then mixed with a large proportion of fine powder consisting usually of inert mineral substances, waxy hydrocarbons and sulfur. The mixture is thus masticated until all its constituents are thoroughly mixed and a smooth homogeneous paste obtained. This process is known as compounding.

Fillers Used in Compounding. Experience has shown that 60 or 70 per cent of mineral filler, or even a greater proportion of rubber substitute, may be added to rubber gum, before the essential qualities of the rubber cease to predominate. The majority of commercial 30 per cent insulating compounds have compositions which fall within the following limits.

Ingredient	Per cent
Rubber	30–32
Whiting	0–30
Zinc oxide	28–67
Litharge	1–12
Ozokerite or paraffin	2– 4

In addition to the above fillers, from 2 per cent to 4 per cent of sulfur is added to the compound, the greater part of which combines with the rubber in the vulcanizing process. Sulfur bearing organic substances are also used for vulcanizing.

Barium sulfate, sublimed white lead, lead carbonate, carbon black, talc, magnesium carbonate, red lead, barium carbonate, black hydro-carbons, and other substances are also used in small quantities.

Applying the Compound to Wires. The rubber compound is applied to the wire by "tubing" machines, or is applied in strips, and the wire thus covered with the compound is coiled up ready for vulcanizing.

Vulcanizing. If exposed for a long time to air or sunlight, rubber loses its elasticity and finally oxidizes completely into resinous matter soluble in acetone. By vulcanization, however, rubber is rendered more or less immune from deterioration by weathering. Vulcanization is the chemical union of rubber gum with sulfur. It takes place at a temperature between 248 and 302 deg fahr.

The coils of wire, covered with the compound as above described, are placed in a suitable chamber to which steam at the proper temperature is admitted. The time required for vulcanization depends upon the thickness of the insulation, the nature of the compound, the temperature and pressure of the steam, etc., ranging from 2 to 8 hours.

Accelerators and Anti-oxidants. Certain classes of organic compounds are used in small amounts to accelerate the cure, thus largely decreasing the investment in vulcanizing equipment for a given production. Anti-oxidants, such as aniline and related compounds, are often added to the mix to increase the useful life of the articles made from it.

Specific Resistance. The specific resistance is not an indication of the quality of rubber insulation as it depends more upon the dryness, the proportion of mineral wax, and the degree of vulcanization, than upon the quality of the ingredients. When the megohms are low they can almost invariably be raised by drying the insulation in a desiccator. The specific resistance of very poor-quality rubber compound, however, sometimes is so low that, when a cable lies in damp earth, sufficient leakage current may flow to permit the passage of water by endosmose, when the conductor is negative to the ground.

Dielectric Strength. The disruptive strength of rubber insulation is generally given as between 350 and 450 kv per in. or about 140 to 180 kv per cm effective a-c values. The pressures which should be used in commercial testing do not depend entirely upon the dielectric strength of the rubber, as air in the rubber or between the rubber and conductors becomes ionized at a pressure of about 30 kv per cm with consequent generation of ozone, which rapidly oxidizes and destroys the rubber. Hence test pressures for rubber insulation, if sufficiently high to permit ionization of the air, should not last long enough to permit the formation of an appreciable amount of ozone.

Specific Inductive Capacity. The specific inductive capacity of pure rubber is about 2.3 (Floy), but the vulcanized compounds used for insulation have specific capacities ranging between 3 and 5, the latter value being nearer the average.

Water Absorption. Rubber contains proteins which, when the rubber is immersed in water, act as membranes to carry the water into the rubber. There are natural electrolytes in the rubber, such as quebrachitol, which go into solution in the absorbed water, the rate of absorption depending on the difference between the external and internal osmotic pressures. Water absorption may be detected by increase of capacitance and conductance while the rubber is immersed in water.

HARD RUBBER OR EBONITE. If, instead of using the small proportions of rubber indicated above for vulcanization, the proportion be increased to between 20 and 35 per cent, a hard material will be obtained which can be used for instrument panels, etc., as it can be machined, drilled, etc. The principal properties will be as follows:

Tensile strength	1000 lb/sq in. or more
Dielectric strength, between flat electrodes	1000 to 2000 volts/mil
Dielectric constant (S.I.C.)	2.0 to 3.5
Resistivity	10^{15} to 10^{18}

Hard rubber is not hygroscopic but is attacked to some extent by oil and ozone. Sunlight reduces its surface resistivity. (See Bureau of Standards Scientific Paper No. 234.) Data on dielectric strength are given by F. M. Farmer, *Trans. A.I.E.E.*, 1913, Vol. 32, p. 2101.

FACTICE. Vegetable oil, such as cotton seed oil, rape seed (colza) oil, corn oil, etc., may be converted into a rubber-like substance by heating to about 470 deg fahr and pouring into it from 30 to 40 per cent by volume of molten sulfur. The mass is stirred until a thorough combination has been obtained, and evolution of gas has ceased. When cooled, the resultant mass of *vulcanized oil* is a soft rubber-like material of low tensile strength but water resistant and unaffected by ozone. It mills readily with rubber and

adds its characteristics in considerable measure. Rubber insulation for high voltages almost invariably contains factice in large proportions, so that it may be ozone resistant.

KOROSEAL is a synthetic rubber developed by the Goodrich Rubber Co. which is highly oil resistant and quite immune to the action of ozone. It is a thermoplastic material, and makes an excellent filling for oil proofing fabrics.

DUPRENE is a synthetic rubber developed by the DuPont Company. It is a chlorinated derivative of acetylene, and is similar in molecular structure to rubber. The advantages of Duprene are its resistance to age brittleness and to the action of oil. The material is permanently flexible and in accelerated aging at high temperature shows superiority. Light mineral oils soften Duprene somewhat but not so seriously as they do rubber. It may be obtained in sheets and is used chiefly for gaskets.

THIOKOL, chemically olein polysulfide, derived from natural gas, is an oilproof rubber substitute made by the Thiokol Corporation. It is unaffected by oil, gasoline, or similar materials. In accelerated aging tests, its life compares with high-grade long-life rubber. The "cold flow" under pressure (as in a gasket) is greater than that of either rubber or Duprene. Because of the composition, Thiokol produces corrosion in contact with copper; and with transformer oil, sludging and acid formation result. It cannot be used as transformer gaskets with usual designs. The chief application is for oil and gasoline hose. It may be used as a surface layer over rubber for gaskets on lubricating oil and gasoline containers. Also, an outside coating of thiokol on rubber-insulated cables is useful for cables subjected to oily conditions.

GUTTA-PERCHA. Gutta-percha is derived from the milky secretion or latex of the bark of certain trees of the order of Sapotaceæ, especially the Dichopsia Gutta, found chiefly in the Straits Settlements and Malaccan Archipelago. The trees are felled just after the rainy season, and the gum collected as it exudes from incisions in the bark. Latex is also extracted from the leaves by digesting them in toluol. The latex is boiled in water and it is then ready for export. Gutta-percha is becoming quite scarce, and practically the whole available supply is used by British cable makers.

The chemical composition of gutta-percha is represented by the formula $C_{10}H_{16}$. It resembles dark brown leather at temperatures between 0 and 27 deg cent. At higher temperatures it softens, and at 65 deg cent it is plastic and capable of being molded or rolled. On cooling it returns to the non-plastic condition. Gutta-percha oxidizes when exposed to the air, changing from dark brown or black to yellowish gray and becoming brittle.

Preparation of Gutta-percha Insulation. For insulating purposes gutta-percha is shredded and squeezed in warm water. It is then kneaded and strained through fine wire gauze and rolled into sheets. Its further refinement is carried on differently by various manufacturers, the processes being more or less trade secrets. Like rubber it is applied to the wire either by a tubing machine or by strips. Unlike rubber it is used in the pure state without mixture with minerals. Gutta-percha is less porous than rubber and therefore more waterproof, a quality which makes it the best material for submarine cables. Its specific gravity is just above unity.

Specific Resistance. The constant K in the formula

$$M = K \log \frac{D}{d}$$

has the value 900 approximately, at 75 deg fahr after one minute electrification. See also article on Rubber.

Temperature Coefficient of Resistance. The temperature coefficient of resistance of gutta-percha is of the same nature as that of rubber (see article on Rubber), i.e.,

$$R_T = R_{75}\,\epsilon^{(75-T)C}$$

where R_{75} is the resistance at 75 deg fahr, R_T the resistance at T deg fahr, and C a constant which varies from 0.065 to 0.085. For values of ϵ^x see Exponential Functions.

Effect of Pressure upon Resistance. Gutta-percha being used principally for submarine cables, the effect of pressure upon its resistance is important. Let R = its resistance at atmospheric pressure, R_p = resistance under pressure of p pound per square inch. Then

$$R_p = R\,(1 - 0.00023\,p)$$

11. PLASTIC INSULATING MATERIALS

Synthetic Resin Products

In recent years great advances have been made in the manufacture of countless varieties of insulating products using some organic filler (cloth, paper, or other fiber) bonded with some type of synthetic resin. The first important material of this type was Bakelite,

developed by Dr. Bakeland. This is a condensation product resulting from the combination of phenol and formaldehyde under certain conditions. The resin in its initial state is thermoplastic and soluble in alcohol-benzol solvent or acetone. Further heat polymerizes the resin and renders it insoluble and infusible. In treating materials with Bakelite, the first stage is used in varnish form and the impregnated filler is then pressed with accompanying heat to cause polymerization.

Many other resins have been introduced since Bakelite was developed. Some are modifications of the phenolic class, but many are of distinct types. A useful series of resins is known as Glyptal. These are made of glycerin and pthalic anhydride. Other types are resorcinal-formaldehyde, furfural-formaldehyde, vinyl resins, and urea resins.

Table 9. Properties of Laminated Phenolic Sheet Materials (N.E.M.A. Standards, 1931)

Grade	Description	Average Tensile Strength, lb per sq in.	Average Flexural Strength, lb per sq in.	Average Dielectric Strength, volts per mil		1,000,000 Cycles			Moisture Absorption Percentage in 24 hr
				Short Time	Step by Step	Power Factor Percent	SIC	Dielectric Loss Factor	
X	Paper base	12,000	21,000	700	500	....	....	....	4.0
P	Paper base	8,000	15,000	600	400	....	....	....	4.0
XX	Paper base	8,000	16,000	700	500	4.5	5.5	0.25	1.3
XXX	Paper base	7,000	15,000	650	450	3.5	5.0	0.18	1.0
C	Heavy fabric base for mechanical purposes	10,000	20,000	150	100	10.0	7.0	0.70	1.7
CE	Heavy fabric base electrical and mechanical	9,500	19,000	425	275	5.5	5.5	0.30	1.5

Table 10. Properties of Typical Laminated Tubing

Description	Color	Specific Gravity	Water Absorption Per cent Increase in Weight after 24 Hours	Ultimate Strength, lb per sq in. Axial Stresses		Dielectric Strength 1/16 Wall, Volts per mil	
				Tensile	Compression	In Oil	In Oil after 24 Hours in Water
Kraft paper and synthetic resin. Applications where machining qualities are desirable. Superior mechanical and electrical properties. Special tools for shapes other than round	Dark tan	1.29	3	11,000	20,000	1000	800
Kraft paper and shellac. For general use (except brush holder tubes) under 75 deg cent. Will collapse at 100 deg cent unless mechanically supported. Resists arcing slightly more than phenolic materials. Made in round and other shapes. Not baked	Brown	1.12	55	8,000	7,000	800	
Fine weave fabric and synthetic resin. Where extra strength and high impact are desired. Has lowest moisture absorption of any grade, and is preferred for most chemical applications	Tan	1.25	2	5,800	22,000	350	300
Kraft paper and synthetic resin	Black	1.29	3	11,000	20,000	650	500

indicative of satisfactory oil as far as laboratory tests can determine. The following values may be taken as representative of acceptable unused transformer oil which is also suitable for most circuit breakers:

Specific gravity	0.898 at 15.5 deg cent
Flash point	132 deg cent
Fire point	149 deg cent
Viscosity (Saybolt)	57 sec at 40 deg cent
	280 sec at 0 deg cent
Pour test	−45.6 deg cent
Demulsibility (resistance to emulsion value)	25 sec
Neutralization value	0.03 mg of KOH per gram

(See A.S.T.M. Test Methods for Oil.)

Maintenance

CAUSES OF DETERIORATION OF OIL IN TRANSFORMERS. The principal causes of deterioration of insulating oil in service are water and oxidation. The oil may be exposed to moisture through condensation from moist air due to breathing of the transformer especially when the transformer is not continuously in service. The moist air drawn into the transformer condenses moisture on the surface of the oil and inside of the tank. The oil may also be contaminated with water through leakage such as from leaky cooling coils or covers. Sludge is an oxidation product, the amount formed in a given oil being dependent upon the temperature and the time of exposure of the oil to the air. By careful refining, the components of oil which are most readily oxidized to form sludge can be removed, so as to provide an insulating oil which will not sludge under normal operating conditions. Excessive temperatures may cause sludging of any transformer oil, regardless of how well it is refined.

Transformer oil which has begun to sludge will continue to do so after it has been purified by means of the centrifuge or filter press, as these methods of purification do not remove the deterioration products which are in process of formation but have not yet been thrown down as sludge. No method is yet available in the field which will remove these products and bring sludged oil back to its original condition when new. Such oil can be refined so as to be equivalent to new oil, but this would require equipment which is available only in an oil refinery. It is not economical to send used oil to the refinery as it will only allow fuel oil price, which would probably be less than the cost of transportation.

Another effect of oxygen is gradually to produce organic or "fatty" acids in oil in service. These should not be confused with the mineral acid such as sulfuric acid used in refining, as in small amounts they do not have a deteriorating effect upon insulation. No method is available in the field of purifying oil of high organic acidity.

In an effort to produce oil which has less tendency to sludge, it is possible to "over-refine" it. Such an oil develops organic acidity, which, when once started, increases rapidly to a point where it becomes a menace to insulation. This high acid development is characteristic of some of the so-called water-white oils.

CAUSES OF DETERIORATION OF OIL IN CIRCUIT BREAKERS. The principal causes of deterioration of insulating oil in circuit breakers in service are:

1. Water.
2. Carbonization of the oil caused by operation of the circuit breaker.

Insulating oils do not absorb water, but they may receive water through condensation on the surface of the oil or on the inside of the tank owing to the entrance of moist air.

All oil in circuit breakers is subject to carbonization due to arcing between the contacts. Part of the carbon formed is deposited on the mechanism and at the bottom of the tank while the remainder continues in suspension in the oil.

Carbonization takes place not only when the circuit breaker opens heavy short circuits, but also whenever an arc is formed, even during such light service as the opening of the charging current of the line, and this latter service repeated may eventually produce enough carbon to be a source of trouble.

The carbon reduces the dielectric strength of the oil, lowers the surface resistance of the insulation if water is present, and also lowers the resistance to emulsification. The carbon may not be detected by the dielectric test, particularly if the oil is free from moisture.

In cold weather, a larger amount of carbon is formed than in warm weather on account of the increased viscosity of the oil at low temperatures. Also the carbon is not as readily dispersed through the oil.

TEST METHOD. (Instructions for testing correspond in general to the recommendations of A.S.T.M.) Dielectric strength.

Apparatus. The transformer and the source of supply of energy shall not be less than $1/2$ kva, and the frequency shall not exceed 100 cycles per second. Regulation shall be so controlled that the high-tension testing voltage taken from the secondary of the testing transformer can be raised gradually without opening either primary or secondary circuit. The rate of rise shall approximate 3000 volts per second. The voltage may be measured by any approved method which gives root-mean-square values.

The test cup for holding the sample of oil shall be made of a material having a suitable dielectric strength. It must be insoluble in and unattacked by mineral oil and gasoline and non-absorbent as far as moisture, mineral oil, and gasoline are concerned.

The electrodes in the test cup between which the sample is tested shall be circular disks of polished brass or copper, 1 in. in diameter and having square edges. The electrodes shall be mounted in the test cup having their axes horizontal and coincident, with a gap of 0.100 in. between their adjacent faces, and with top of electrodes about $1^1/_4$ in. below the top of the cup.

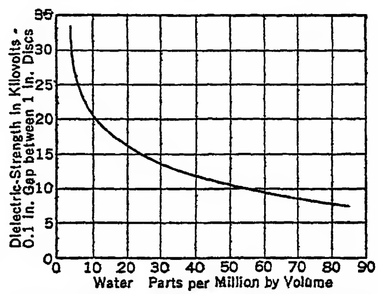

FIG. 4. Relation between Dielectric Strength and Amount of Water in Insulating Oil

Procedure. (*a*) The electrodes and the test cup shall be wiped clean with dry calendered tissue paper or with a clean dry chamois skin and thoroughly rinsed with oil-free dry gasoline or benzine until they are entirely free from fibers.

(*b*) The spacing of electrodes shall be checked with a standard round gage having a diameter of 0.100 in. and the electrodes then locked in position. Care shall be taken not to touch the electrodes with the gage or in any other manner after cleaning the electrodes and cup, so as to avoid any possible contamination.

(*c*) The test cup shall be filled with dry gasoline or benzine and voltage applied with uniform increase at the rate of approximately 3000 volts (rms) per second until breakdown occurs. If the dielectric strength is not less than 25 kv, the cup shall be considered in suitable condition for testing the oil. If a lower test value is obtained the cup shall be cleaned with gasoline and the test repeated.

(*d*) The temperature of the test cup and of the oil when tested shall be the same as that of the room which should be between 20 and 30 deg cent (68 and 86 deg fahr). Testing at lower temperatures is likely to give variable results which may be misleading.

(*e*) The sample in the container shall be agitated with a swirling motion to avoid introducing air, so as to mix the oil thoroughly before filling the test cup. This is even more important with used oil than with new oil, as the impurities may settle to the bottom and the test may be misleading.

(*f*) The cup shall be filled with oil to a height of no less than 0.79 in. (20 mm) above the top of the electrodes.

(*g*) The oil shall be gently agitated by rocking the cup and allowing it to stand in the cup for 3 min before the first and 1 min before each succeeding puncture. This will allow air bubbles to escape.

(*h*) Voltage shall be applied and increased uniformly at a rate of approximately 3000 volts (rms) per second until breakdown occurs as indicated by a continuous discharge across the gap. (Occasional momentary discharges which do not result in a permanent arc may occur; these should be disregarded.)

(*i*) Provision shall be made for opening the circuit as promptly as possible after breakdown has occurred in order to prevent unnecessary carbonization of the oil. After each puncture, the testing vessel shall be jarred to loosen particles of carbon adhering to the electrodes and the oil gently agitated but not with sufficient violence to introduce air bubbles.

(*j*) Five breakdowns shall be made on each filling after which the vessel shall be emptied and refilled with fresh oil from the original sample. The test shall be continued until the averaged values of at least three fillings do not differ from their mean by more than 10 per cent.

PURIFICATION. The purification of oil used in circuit breakers and transformers consists principally in the removal of water, carbon, and sludge and the restoration of its

resistance to emulsification, putting the oil in the best condition to separate out any water which may later be introduced.

Three types of equipment for simple purification of oil in circuit breakers and transformer service are in general use, the centrifuge, the blotter filter press, and the combination centrifuge and filter press. The combination of centrifuge with chemical treatment is particularly well adapted for the purification of carbonized circuit breaker oil. The application of chemical treatment for purifying sludged oil or oil having high acidity for transformer service is still in the experimental stage.

Blotter Filter Press. The filter press is essentially a number of sets of filter papers in parallel, each set containing several thicknesses. The oil is pumped through the filter paper which absorbs the water and strains out the sediment.

The filter press is not intended to remove large amounts of free water from the oil. Obviously the changing of filter papers necessary for obtaining dry oil would so reduce the capacity as to make this method of purification impractical. In such cases the water may be removed by a centrifuge, or should be allowed to settle out and be drawn off from the bottom of the container before passing the oil through a filter press.

Filtering through blotters does not materially reduce organic acidity or improve resistance to emulsification except as the latter is affected by the presence of carbon, although the dielectric strength may be restored to a satisfactory value.

The Centrifuge is the most convenient equipment known for removing water from oil. It also removes solid material other than finely divided carbon. The temperature of the oil should be maintained at 48.9 to 51.7 deg cent (120 to 125 deg fahr) in order to insure removal of all the water at full capacity of the machine. A higher temperature gives no advantage and, if excessive, is harmful to the oil. (A 6-kw heater will raise the oil about 15.6 deg cent (60 deg fahr) per 100 gallons per hour.) The centrifuge equipment may be arranged to act as a separator, discharging the oil and water by different outlets, or as a clarifier, discharging the oil but retaining in the bowl, the water and other impurities. When there is considerable water in the oil it should be operated as a separator.

The centrifuge will remove the coarser particles of carbon from the oil. For removal of fine particles of carbon, the blotter filter press or centrifuge with suitable chemical treatment should be used.

Soluble impurities developed by constant use of the oil in circuit breakers or transformers *can be removed only by chemical treatment.*

The Combination Centrifuge and Filter Press. The combination centrifuge and filter press meets the need for a compact unit which may be used advantageously in the purification of insulating oil. It consists briefly of a motor-driven centrifuge, electric heaters, regulating float valve, pumps and filter press or presses, mounted upon a truck.

The centrifuge and chemical treatment of circuit-breaker oil includes chiefly the agitation of warm oil with a solution of silicate of soda, the passing of this mixture through a centrifuge operating as a separator which removes the sodium silicate solution containing nearly all the impurities, then to a mixing tank where it receives a definite amount of inert earth, and finally passing the oil through another centrifuge operating as a clarifier, which removes the inert earth and any impurities or moisture present. The process is continuous.

13. OTHER LIQUID INSULATING MATERIALS

INSULATING VARNISHES. A varnish is generally considered a solution of gums (fossil or synthetic) in (1) volatile solvents or (2) drying oils. The evaporation of the solvent in the first type (spirit varnishes), and the oxidation (or polymerization) of the oils in the second type (oil varnishes), leave a hard smooth film which is a protection against moisture and weak chemical solutions. Varnishes may be differentiated from paints in that varnishes usually contain no pigment. Varnishes may, however, be used as vehicles for pigments, forming enamel paints.

Insulating varnishes have good electrical properties and also serve to protect and preserve the insulating properties of other materials used as insulation. Most of the widely used materials, such as cotton, paper, wood, and asbestos, are excellent insulators when dry, but absorb moisture readily, and when moist become more or less conducting. Varnishes fill air spaces in coils and offer better heat conductivity than air, as well as cementing coils together.

Spirit Varnishes are usually those composed of shellac (various grades) or synthetic resins dissolved in alcohol or other volatile solvents. They are used for rapid air-drying applications and find use more as finishes or surface coatings than impregnating purposes. They usually possess low flexibility and good cementing properties.

Oil Varnishes consist of varnish gums or resins, such as copal, succin, dammar, mastic, combined with a vehicle compounded from linseed oil and tung oil. In black varnishes, clear gums are replaced by asphaltic materials or pitches. The drying time is governed by the proportion of gums and oils and by the quantity of oxidizing agents or driers in the varnish. The greater the proportion of oils, the longer the drying time.

Some of the quick air-drying black varnishes may contain no drying oil. Such varnishes are neither oil type nor spirit varnishes and may be termed asphaltic varnishes. They may consist of an asphaltic base and a solvent derived from petroleum or coal tar.

In the manufacture of spirit varnishes, the gums are cut cold in the solvent; the oil type and asphaltic varnishes are made by fluxing the various ingredients together in a kettle at a high temperature.

Varnishes to be satisfactory must possess the desirable properties in all three states—as a liquid, during drying, and when solid. The most important characteristics to consider are:

Liquid	While Drying	Solid
Color	Spreading	Hardness
Viscosity	Draining	Toughness
Specific gravity	Drying time	Cementing ability
Per cent solids	Relation of surface to subsurface drying	Dielectric strength
Nature of solvent	Chemical action on metals or insulating materials	Softening temperature
Penetration		Resistance to water, oil, chemicals
Flow		
Tendency to skin in tanks		

It is not possible to combine in one varnish the maximum degree of all desirable attributes. There are, therefore, a number of useful types of insulating varnish, adapted for particular needs. For example, it is not yet possible to make a quick-drying varnish that has the ultimate degree of flexibility and heat life. Further, a plastic varnish is not considered the best for a hard surface finishing material.

For most electrical work the following varnishes cover the requirements satisfactorily: a clear and a black varnish for both air drying and baking, and a plastic coil impregnation varnish, making five varieties (see Table 11). These varnishes are useful as well for finishing of apparatus (metal and insulation) to provide good appearance and a surface easily kept clean.

Air-drying varnishes do not produce as hard a moisture-resistant coating as baking varnishes under usual conditions but are necessary for apparatus that cannot be baked or for repairs away from the factory. The black varnishes are generally more moisture resistant than the clear but are less oil resistant. Black varnishes are somewhat superior to clear varnishes in dielectric properties.

Varnishes may be applied by brushing, dipping, or spraying. Coils are usually dipped for sufficient time to drive out air, then drained, and then baked. The temperature of baking depends on many factors such as time allowable and type of material. Short-time baking (15 min) may be done up to 200 deg cent. A more usual temperature for baking time of 1 to 3 hours is 150 deg cent. Good oven circulation to remove solvent, and thus hasten drying, is important. Vacuum drying of coils is frequently employed to remove moisture and air. The impregnating material may be admitted to the tank while under vacuum to prevent entrapping air.

Testing of Insulating Varnishes. It is very difficult to describe a varnish comprehensively by any list of physical properties. The true test of a varnish is its performance in the application chosen. However, a number of standardized tests have been worked out by A.S.T.M. for evaluating insulating varnishes. They are of importance in checking uniformity and as a general basis for specifications. They cover: specific gravity; viscosity; flash point; evaporation; draining; drying time; dielectric strength; water absorption; heat endurance (life); acid, alkali, and oil resistance; and non-volatile content.

WIRE ENAMELS. Insulating varnishes with special characteristics are used in coating wires with an insulating film. Wire enamels are composed of fossil gums (in most cases) combined with drying oils. They differ from usual insulating varnishes in containing less oil (linseed and tung) and are thinned with coal-tar solvents quite similar to kerosene instead of the naphthas.

In the coating operation, the wire is passed successively through the tank of liquid enamel ("dope pan") and vertically through a baking chamber, over sheaves, and the cycle is repeated. From three to six layers are applied, depending on the size of wire and the service required. Baking is best done by controlled electric heat in the range 400–500 deg cent. The speed of wire travel depends on height of baking oven, tempera-

Table 11. Insulating Varnishes

	Drying Time, hours	Moisture Resistance Rating	Oil Resistance Rating	Acid Resistance, seconds till failure		Dielectric strength, volts per mil		Life at 110 deg cent, hours	Chemical Analysis										Applications
				H_2SO_4	HNO_3	Dry	Wet		Rosin	Asphaltum	Lime	Linseed Oil	Chinawood Oil	Lead and Manganese	Iron Oxide Dryer	Benzine 50 to 60 deg Baumé	HeavyBenzine 40 to 45 deg Baumé	Turpentine	
Black plastic baking	4	90	65	72	150	1923	947	770											Plastic insulator for coils and stators
Black coil baking	5	90	80	128	65	1890	610	528	6.1%	14.9%		23%	11.5%	0.77%		44%			For coils, armatures, and wound apparatus, also finish
Clear coil baking	1	55	100	61	40	1722	403	600	9.4%		0.51%		43.3%	1.02%		46%			For wound armatures and cloth finish
Black air dry	4	65	0	107	141	1642	527	24		29%		13%			0.43%	59%	54%		General use where baking cannot be done
Clear air dry	4	75	100	27	22	1128	246	675	8.2%			3%	27%	1.4%		55%		6.1%	General use where baking cannot be done

Specific gravity of all varnishes, 0.835 or 0.850. Thinner for all varnishes, benzine.

ture, and size of wire. Heavy wires (No. 10 A.W.G.) may travel 12 ft per min, whereas fine wire (No. 40–44 A.W.G.) may pass through at 80 ft per min.

Common American enamels are mahogany red in color when properly baked. Color is a fair but not infallible indicator of degree of bake or cure, since the color changes with time. Underbaked wire (copper red) is tougher and will elongate without rupture of enamel, but may be less resistant to abrasion and not oilproof. On the other hand, a black wire (overbaked) will probably be brittle but harder and more oil resistant. A good wire enamel properly baked should have the following characteristics:

a. Should produce a uniform coating—no beading and no thin spots.

b. Should be flexible to withstand elongation in coil winding. Should show no breaks when wire is stretched to breaking point.

c. Should resist abrasion.

d. Should have reasonably high dielectric strength (1500 volts per mil).

e. Should withstand hot oil and varnish. Withstand varnish at 80 deg cent for 16 hours without softening.

f. Should have long life. Elongation should not decrease appreciably when wire is stored for 6 months.

SHELLAC. Shellac is a resinous substance produced by insects of the plant lice species. These insects suck the sap of certain trees in India, and convert this sap into a resin which is exuded through the pores and finally completely surrounds the insects. Being a product formed by natural processes, it is subject to a variety of ills caused by climatic changes during its formation, and by natural enemies such as parasitic and predatory insects which prey on the minute shellac insects. The branches on which the insects lived are removed from the trees and the shellac incrustations scraped off. In this form, with some twigs, bark, and insect bodies included, the shellac is known as sticklac. This is ground into smaller pieces and washed thoroughly in water to remove dirt and all traces of the red coloring matter known as lac dye. After washing, the material, pale orange in color, is known as seedlac. The large granules are used in the highest grades of orange shellac; the smaller dark granules are marketed as lower grades of orange shellac and garnet shellacs. After purification, the lumps of shellac resin are packed in bags for shipment. When used, the lumps are ground and cut in alcohol, forming a spirit varnish. Some grades of shellac are dissolved and then dried to flake form for easy solution. The various grades of shellac differ in color, flow properties, and freedom from impurities such as dirt, dye, and wax. Shellac which has poor flow characteristics is sometimes improved by addition of rosin. For some purposes, this does no harm, but in general the adhesive and mechanical strength is impaired by rosin additions.

Shellac is most frequently used in varnish form, applied to insulating materials (paper, cloth, yarn, or asbestos). The treated material is subsequently heated to melt the dried shellac and cement the parts together. To obtain satisfactory uniformity of performance certain tests have been developed for acceptance of shellac.

Flow Test is an important indication of shellac fluidity. It is made with a device in which 2 grams of powdered shellac is melted and at 125 deg cent allowed to flow down a trough inclined 60 deg. The time to flow 5 in. is measured. Typical results of usual grades are shown below.

VSO orange shellac	60– 100 sec at 125 deg cent
CVTN orange shellac	100– 200 " " " " "
Pale orange shellac	80– 200 " " " " "
Garnet orange shellacs	200–1500 " " " " "
Soda lac	Too sluggish to flow

Polymerizing Test. The length of time a shellac retains its fluidity at high temperatures (125–250 deg cent) before becoming infusible is important in selecting shellacs for uses where repeated melting is necessary.

Representative figures of "life" (time until "rubbery" consistency) at various temperatures are:

Shellac	Life at 125 deg cent, min	Life at 150 deg cent, min	Life at 200 deg cent, min
VSO orange shellac	60	36	10
CVTN orange shellac	35	14	6
Pale orange shellac	50	30	9
Garnet shellac	20	10	4
Soda lac	40	20	7

Viscosity Test. Used in determining solubility.

Volatile Test. A measure of amount of gas evolved.

SOLVENTS. It is important to know the insulating characteristics of ordinary solvents, since some quantity of solvent is usually still present after coils are baked or insulating structures finished.

Because of its high affinity for water, alcohol must be thoroughly removed from spirit varnish impregnation. In deep coils this is difficult, and drying operations must be carefully done.

Turpentine, benzine, toluol, benzol, and other related solvents do not mix with water and are good insulators. It is not therefore required for insulating reasons that all solvent be completely removed in impregnation processes. Evaporation will continue for some time. For mechanical reasons (to prevent throwing of "wet" varnish or distortion of coils) it is important to carry evaporation far enough to produce a hardening of the varnish or compound. Under some conditions, organic acids develop in "wet" varnish.

LINSEED OIL, used as an impregnating material and as a major constituent of paints and varnishes, comes from flaxseed. The density at 15 deg cent is 0.934. Linseed oil dries principally by atmospheric oxidation, finally to a hard gum. With "raw" linseed this process in air is quite slow. "Boiled" oil will oxidize fairly rapidly in air. The action is accelerated by heat or chemical driers. (See Insulating Varnishes.) Linseed oil is commonly used to impregnate wood. It produces a moisture-proof product, capable of withstanding weather. Impregnation is usually done hot (60 deg cent) to aid in penetration. Baking oxidizes the oil to give a satisfactory surface coat.

NON-DRYING OILS, such as castor oil, rosin oil, or olive oil, are good insulators, but almost always are used in combination with other materials.

TUNG OIL (china wood oil) comes from the nuts of an oriental tree and is used mainly in the manufacture of varnishes. It hardens chiefly by polymerization rather than oxidization and thus differs from linseed oil. It may be used for impregnating coils or wood.

14. GASES

Gases, when stressed below rupturing gradients are excellent insulators. Their specific inductive capacity under normal atmospheric conditions is nearly the same as a vacuum, being less than 1 per cent greater. Dielectric strength is rather low, being 31 kv (crest) per cm for air in a uniform electrostatic field. Where the field is non-uniform, local breakdown (corona) induces complete rupture at much lower values. The dielectric strength increases directly with pressure.

AIR. Air occurs as an insulator on every piece of electrical apparatus. The distance externally between live parts or between terminals and a grounded part must be great enough to prevent breakdown or excessive leakage in an air path. It is true that frequently the effect of a solid insulation creepage surface is important but in many cases air is the effective external dielectric. In solid insulation, air is a detriment. Its low specific inductive capacity causes concentration of voltage gradient on the air layers or pockets (inversely proportional to specific inductive capacity) and may lead to corona and progressive breakdown.

The dielectric strength of air gaps depends largely on the type of electrodes with their local electrostatic fields. Needle point gaps have a fairly uniform strength of approximately 4 kv per cm. Sphere gaps or gaps between large curved surfaces have much higher unit breakdown strength, especially at spacings less than the diameter of the spheres. (See Sphere Gaps.) With most types of air gaps, humidity, air density, and frequency greatly influence the dielectric strength.

CARBON DIOXIDE. Compressed carbon dioxide has been used as an insulator in high-voltage condensers for apparatus used in measurement of power factor and capacitance. It is an inert gas, obtainable in a relatively pure state and sometimes used as a gaseous insulator in containers.

NITROGEN. There is little difference in the dielectric properties of the common gases. The choice usually depends on cost or chemical properties. Nitrogen is inert and finds application as an atmosphere in sealed transformers. It prevents absorption of oxygen by the oil and thus eliminates formation of organic acids and sludge ("Inertaire" type of transformers).

HYDROGEN. Because of its high specific heat (3.41 compared to 0.237 for air), hydrogen is useful as a dielectric to absorb heat from electrical machinery. It is used in a closed system for cooling large generators. Care must be taken to keep a positive gas pressure in the system to prevent influx of sufficient air to produce an explosive mixture.

Although the dielectric strength of gases varies roughly as the pressure, there are small differences in behavior of the various common gases. Considering the strength of

air as 1.00 at the various pressures, the following table shows the relative dielectric strengths as a factor of the air values.

Relative Dielectric Strengths of Gases (Air = 1.00)
(Wolf)

Atmospheres Pressure	Carbon Dioxide	Nitrogen	Hydrogen
1	1.20	1.16	0.87
2	1.10	1.15	0.76
3	1.05	1.15	0.72
4	1.03	.1.14	0.69
5	1.02	1.14	0.68

MAGNETIC MATERIALS

15. CLASSIFICATION

Materials may be assigned to one of three classes on the basis of magnetic properties, namely:

(*a*) **Diamagnetic,** having a permeability less than that of a vacuum. Bismuth is a material in this class.

(*b*) **Paramagnetic,** having a permeability slightly greater than that of a vacuum, and approximately independent of the magnetizing force.

(*c*) **Ferromagnetic,** having a permeability considerably greater than that of a vacuum, which will in general be a function of the previous magnetic history of the material.

Only the ferromagnetic materials find general commercial application on the basis of their magnetic properties.

Definitions

The following general concepts and definitions, which have been adopted by the A.S.T.M., are useful in considering the magnetic properties of materials.

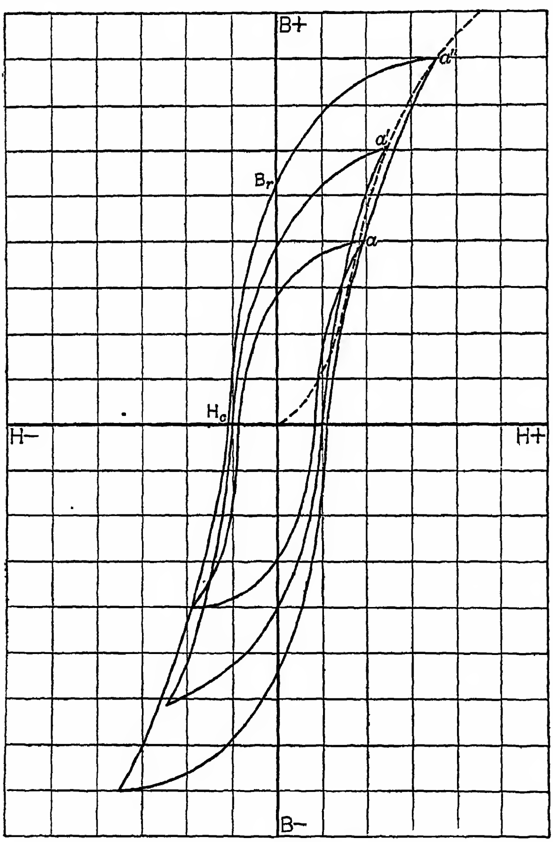

FIG. 1. Typical Hysteresis Loops

Aging of Magnetic Materials: The normal or accelerated change in magnetic properties of a magnetic material under continued normal or specified artificial aging conditions. When used in reference to core loss, this term, unless otherwise modified, implies an increase in loss. When used in reference to permeability or remanence, the term, in a positive sense, indicates a decrease in these quantities.

Aging Coefficient: The percentage change in the standard core loss after continued heating at 100 deg cent for 600 hours.

Coercive Force, H_c: The reversed magnetizing force (distance to H_c in Fig. 1) that is just sufficient to reduce the residual induction in a material to zero. Coercivity is the property of a material, measured by the coercive force required to reduce to zero the induction remaining after the removal of an applied magnetizing force corresponding to the saturation induction for the material.

Core Loss (Iron Loss), W: The power expended in a magnetic material subjected to a varying induction. The standard core loss, $W_{B/f}$ is the total power in watts per pound expended in the magnetic material which is subjected to a harmonically varying induction of a specified maximum value B

and of a specified frequency f. The usual units are watts per pound at 60 cycles and 10,000 gausses expressed as $W_{10/60}$.

Eddy Current Loss, W_e: That part of the core loss due to currents circulating in the magnetic material as a result of electromotive forces induced by the varying induction.

Hysteresis Loss, W_h: That part of the core loss represented by the energy converted into heat as a result of magnetic hysteresis.

Intrinsic Induction in a Ferromagnetic Material (Ferric Induction), B_i: For a given value of the magnetizing force, the excess of the normal induction in the material over that in vacuum.

Normal Induction in a Ferromagnetic Material (Normal Induction), B: The induction for a given magnetizing force when the material is in a symmetrical cyclic condition with respect to the magnetizing force, that is, when the material as a result of previous magnetic experience has no magnetic bias. The magnitude of the normal induction for a given magnetizing force is the same for both positive and negative values of the magnetizing force. Unit: gauss.

Permeability, μ: That property of an isotropic medium which determines, under specified conditions, the magnitude relation between magnetic induction and magnetizing force in the medium. Permeability is measured as the ratio of the magnetic induction to the magnetizing force.

Permeability Differential, μ_d: The ratio of the positive increase of normal induction to the positive increase of magnetizing force when these increases are vanishingly small.

Permeability, Incremental, μ_Δ: The ratio of the cyclic change in induction to the corresponding cyclic change in magnetizing force when the mean induction differs from zero.

Permeability, Initial, μ_o: The normal permeability when both the magnetizing force and the induction are vanishingly small.

Permeability Intrinsic, μ_i: The ratio of the intrinsic induction to the corresponding magnetizing force.

Permeability, Normal, μ: The ratio of the normal induction to the corresponding magnetizing force.

Permeability, Reversible, μ_r: The incremental permeability when the change in induction is vanishingly small.

Permeability, Space: That factor which expresses the ratio of magnetic induction to magnetizing force in vacuum. In the cgs electromagnetic system of units the permeability of a vacuum is arbitrarily taken as unity.

Permeance, P: In a portion of a magnetic circuit extending between two equipotential surfaces, the ratio of the flux through any cross-section, to the magnetic potential difference between the surfaces, when taken within the portion under consideration.

Permeance, $$P = \frac{\phi}{F} \text{ is equivalent to } \frac{\mu A}{L} \text{ for uniform } \mu$$

where μ = permeability; A = area in square centimeters, and L = length in centimeters.

Reluctance, R: The reciprocal of permeance.

Reluctance, $$R = \frac{F}{\phi} \text{ is equivalent to } \frac{L}{\mu A} \text{ for uniform } \mu$$

Reluctivity: The reciprocal of the permeability of a medium.

Remanence: The magnetic induction remaining in a magnetic circuit after the removal of an applied magnetizing force. If there is an air gap in the magnetic circuit, the remanence will be less than the residual induction. Unit: gauss.

Residual Induction, B_r: The magnetic induction (distance (OB_r) in Fig. 1) remaining in a symmetrically cyclicly magnetized magnetic material when the effective magnetizing force has been reduced to zero at every point. Unit: gauss.

Retentivity: That property of a material measured by the residual induction corresponding to an applied magnetizing force sufficient to produce saturation induction in the material. Unit: gauss.

Saturation Induction, B_s: The maximum intrinsic (ferric) induction possible in a material. Unit: gauss.

Criteria of Magnetic Quality

In judging the suitability of magnetic materials for various applications it is customary to make use of various standard forms of data.

Normal Induction Curves or tables constitute the locus of the extremes of a series of hysteresis loops (O–a–a'–a'', etc., in Fig. 1). A typical normal induction curve for 1 per cent silicon steel is shown in Fig. 2. In using such data the effect of air gaps or joints in the magnetic circuit should be considered, since these joints may have appreciable reluctance.

Normal Permeability Curves or tables are obtained from the normal induction curves by dividing the flux density in gausses by the magnetizing force in oersteds.

$$\mu = B/H$$

A typical normal permeability curve is shown in Fig. 2.

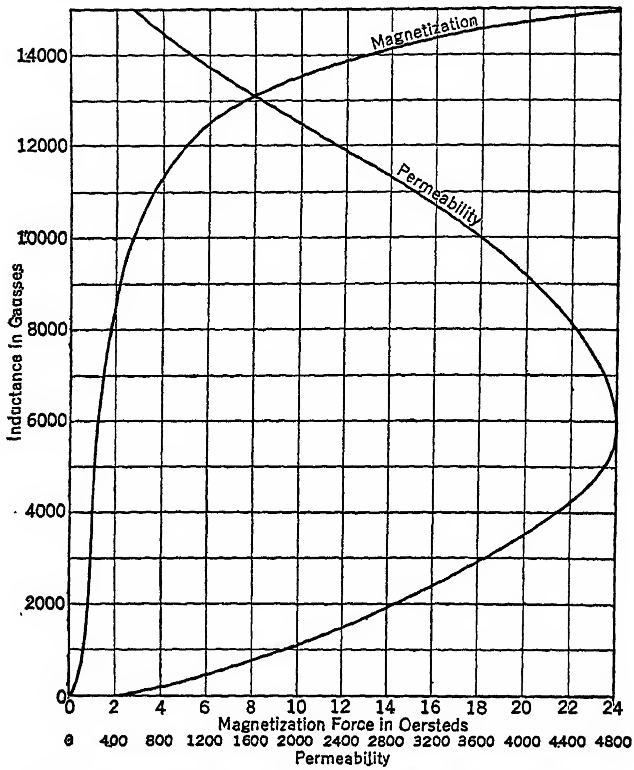

FIG. 2. Magnetization and Permeability Curves for Low Silicon Steel

Hysteresis Loops represent the relation, in an initially demagnetized material, between induction and magnetizing force, as the induction is varied from a positive maximum to a negative maximum and back to the initial point. Fig. 1 shows a family of such hysteresis loops taken at various values of peak induction. The areas of such loops represent the loss due to magnetic hysteresis and are sometimes used in comparing magnetic materials. The values of the residual induction and coercive force, criteria particularly useful in selecting permanent magnet materials, may also be found from such loops.

Iron Loss Curves or tables are usually prepared to show the relation between the summation of the hysteresis and eddy current components of the core loss, and maximum induction, at a definite frequency, and when the induction is varying harmonically. In using iron loss data obtained from tests on small samples, it is important to remember that extra losses, not present in the test sample, will be found in most apparatus due to eddy currents in various parts of the magnetic path or in the structural members, stray flux in structural parts, and possibly to harmonics in the flux wave.

Incremental Permeability Data are frequently useful in the design of equipment where an alternating flux is superposed on a steady flux. The length and number of the joints or air gaps in the magnetic circuit must be carefully considered in using such data, which are frequently of much value in the design of radio equipment, such as audio transformers and filter reactors.

The value of permanent magnet materials is frequently judged on the basis of the value of the product of the residual induction and the coercive force available at that

induction, at that point in the demagnetization quadrant of the hysteresis loop where this product is a maximum. This figure represents the maximum amount of useful energy that a magnet material can deliver; it is sometimes known as the *maximum energy product* and written (B_dH_d) max.

Classes of Commercial Magnetic Material

Magnetic materials may be divided into three groups for the sake of convenience of description, namely: (*a*) the *non-retentive* or magnetically "soft" materials, (*b*) the *retentive* or magnetically "hard" materials, and (*c*) those *special magnetic materials* having properties suited only to certain special applications.

(*a*) The non-retentive or magnetically "soft" materials are by far the most important, on the basis of the amount used. Materials falling in this class range from cast iron, which is one of the poorest, to Hipernik, which is one of the best, and include also cast steel, ordinary low-carbon sheet or plate, ingot iron, and the electrical (silicon) sheet materials. These materials are in general characterized by low coercive force, comparatively low hysteresis loss, relatively high permeability, and, usually, a fairly high saturation induction; they are used in the electromagnetic circuits of electrical apparatus.

(*b*) The retentive or magnetically "hard" materials find application in the permanent magnets of meters and relays, sound-reproducing units, magnetos, and other equipment where a steady magnetic field is required and it is not convenient to obtain this field electromagnetically. These materials are characterized by high coercive force, comparatively high hysteresis loss, and, usually, low permeability.

(*c*) Special alloys include those materials having special temperature-permeability relations, used in compensating for changes in flux in a magnetic circuit due to temperature changes, materials having unusually good properties only at very low inductions, materials especially suited to operation at very high flux densities, and those materials which can be used at very high frequencies.

16. NON-RETENTIVE MATERIALS

General Considerations

EFFECT OF IMPURITIES. Generally speaking, the magnetic properties of iron and its alloys are adversely affected by the presence of impurities; carbon, sulfur, and oxygen tend to increase the hysteresis loss and lower the permeability at all inductions. Manganese, phosphorus, and copper have little effect if present in small quantities, but, with the exception of cobalt, all additions to pure iron tend to lower the saturation induction and the permeability at high flux densities. Silicon, aluminum, and arsenic tend to decrease the hysteresis loss and to improve the permeability at moderate and low flux densities, largely because of the elimination of oxygen and other impurities; but even these elements impair the permeability at high flux densities. Silicon is also of considerable value because it increases the resistivity of the alloy and, therefore, reduces the eddy current losses. (Aluminum and arsenic act in the same way, but are seldom used.)

EFFECT OF MECHANICAL STRAIN. A stress beyond the elastic limit tends to increase the hysteresis loss and reduce the permeability of magnetic materials. This effect is likely to be roughly proportional to the amount of distortion or strain, and usually the best magnetic materials are the most sensitive to mechanical abuse. Shearing or punching strains will increase the 10-kilogauss, 60-cycle loss of a 1 $^3/_{16}$-in. wide strip of silicon steel 10 or 15 per cent and will decrease the permeability at this induction more than 30 per cent. This effect is greater the thicker the material, and is likely to be more marked on the softer grades. The percentage effect of shearing or punching is, of course, an inverse function of the width of the piece sheared. It may be very large in narrow sections such as are found in the teeth of small motors.

Stresses within the elastic limit will change the magnetic characteristics of materials. These changes may improve or impair the magnetic properties, depending on the kind and the amount of the stress, the induction at which the test is made, and the kind of material. Changes in magnetic condition are likewise reflected in changes in the length, or, if confined, in the stress on such materials. These effects are usually small, but may become significant at low inductions or for very high-quality materials.

EFFECT OF DIRECTION OF GRAIN. Electrical sheet or strip steels are likely to show an appreciable change in properties depending on the direction of the flux in the material relative to the final rolling direction. Usual sheet or strip material will show 10 or 15 per cent higher loss when test strips are cut perpendicular to the direction of final rolling than when they are cut parallel to this direction, and the cross-grain samples will

have 20 to 30 per cent lower permeability. Samples sheared at 45 degrees to the direction of rolling usually show loss and permeability characteristics not far different from the straight-grain specimens.

EFFECT OF TEMPERATURE. The magnetic properties of iron and iron silicon alloys are only slightly affected by ordinary temperature changes. In general, the permeability at low and moderate flux densities is improved, and the hysteresis loss is reduced, as the temperature is raised. These changes are greater at low flux densities, but may usually be neglected in the commercial application of materials over ordinary temperature ranges. Iron and the silicon iron alloys become non-magnetic at about 750 deg cent and the magnetic properties are in general more seriously impaired as temperatures of about 500 deg cent are exceeded. The magnetic properties of materials are sometimes impaired after being held for some time at temperatures of the order of 100 deg cent. This "aging" effect used to be of considerable importance, but electrical steels produced today are not seriously affected.

EFFECT OF HEAT TREATMENT. It is usually possible to effect a marked improvement in the magnetic properties of materials by a proper heat treatment or annealing cycle. This heat treatment usually involves heating the material to a suitable temperature, holding at this temperature for a short time, and cooling slowly. The best annealing temperature, if only the release of punching strains is desired, will usually be about 725 deg cent. The punchings can be held at this temperature for several hours, and cooled at a rate of about 30 deg cent per hour. It is important that every precaution be taken to exclude oxidizing or carburizing gases from the material while it is above 600 deg cent. This is effected by either placing the material to be annealed under a tightly sealed metal box, or, if an electric furnace, by supplying an inert or reducing atmosphere to the annealing chamber.

If the material to be annealed has been given no other annealing treatment, the maximum temperature will range between 750 and 900 deg cent for such materials as cast iron, cast steel, ordinary structural or low-carbon steel, "pure" iron, and low-silicon steel. High-silicon steel is annealed at temperatures ranging over 1000 deg cent, and Hipernik at temperatures above 1200 deg cent. The importance of proper atmospheric control increases as the annealing temperature is increased.

IRON LOSSES. When a changing magnetic flux is established in a magnetic material, heat is developed through (*a*) magnetic hysteresis and (*b*) eddy currents.

(*a*) The hysteresis loss (W_h) of a homogeneous magnetic material, which is proportional to the area of the hysteresis loop, has been shown by Steinmetz to be given by the empirical relation

$$W_h = pVfB^x_{\max}$$

where p is the Steinmetz hysteresis coefficient; V is the volume of iron, in cubic centimeters; f is the frequency of the alternating flux, in cycles per second; B is the maximum flux density, in gausses; x is the hysteresis exponent; and W_h is the hysteresis loss in ergs per second.

Values of p are given elsewhere in this section. The values of the hysteresis exponent may be taken as 1.6 over a range of 1000 to 12,000 gausses. At lower inductions the exponent approximates 2, and at higher induction it may considerably exceed this figure. The hysteresis loss is not appreciably affected by the shape of the wave form, according to M. G. Lloyd, provided the voltage wave does not pass through zero more than twice per cycle.

If an alternating flux is superposed on a steady flux or if an alternating flux oscillates about some induction other than zero the hysteresis loss may be considerably increased, depending on the amount of the flux displacement. When a high-frequency flux is superposed on a low-frequency flux, the total hysteresis loss is likewise increased.

(*b*) The eddy current loss is the result of circulating currents set up in a magnetic material due to the changing flux in the material. The eddy current loss, W_e, is given by the expression

$$W_e = Kf^2B^2t^2$$

and where "skin" effect is slight it has been shown that theoretically

$$W_e = \frac{f^2B^2t^2}{6e \times 10^{16}}$$

where f is the frequency, in cycles per second; B is the induction, in gausses; t is the thickness of the sheets, in centimeters; and e is the resistivity, in ohm-centimeters.

However, a theoretical figure for the eddy current loss as computed by this method is usually far less than that determined by actual test, and no completely satisfactory explanation for the discrepancy has been advanced. Four per cent silicon steel may

* A.S.T.M. Standard, not quite actual.

† For magnetic sheet of low silicon content (2% and less) the table of sheet iron gages and weights should be used. For material of medium and high silicon grades (over 2%) the gage dimensions in the sheet iron table are satisfactory but the weights should be multiplied by 0.975.

‡ Seventy-eight per cent nickel.

§ Fifty per cent nickel.

‖ The guaranteed maximum loss at 10,000 gausses, 60 cycles, in 29 gage, is used to designate the grade of electrical sheet steel.

show more than double the calculated eddy current loss, and 50 per cent excess of test over calculated values is not uncommon for ordinary open-hearth sheet and low-silicon steel. Eddy currents tend, by virtue of their counter magnetomotive force, to damp out flux in the center of the cross-section of a magnetic material. Rosenberg has shown that, when this "skin effect" is large, the flux penetration a is

$$a = 5000\sqrt{\frac{e}{\mu f}}$$

where a is the flux penetration, in centimeters; e is the resistivity in ohm-centimeters; f is the frequency; and μ is the permeability. Although probably not very accurate, the formula is very useful in that it will indicate at least the order of magnitude of the flux penetration.

Curves and Data on Commercial Magnetic Materials

In using data on commercial magnetic materials it is important to remember that the magnetic properties of all such materials are likely to vary considerably, depending upon chemistry, kind and amount of mechanical work done on the material, heat treatment, and factors at present beyond control. It is impossible to give exact figures representing the various magnetic characteristics, and the values presented (Tables 1–6) will be those corresponding to the average of good practice. In general, the range over which the values will fluctuate will be smaller for the materials of higher magnetic quality. Silicon steel sheets, for example, will usually show variations in standard iron loss of less than 10 per cent, although permeability figures for this class of material will vary over a considerably wider range. In general, both hysteresis losses, and low and moderate flux

NOTE: To find the approximate iron loss at any induction or frequency, multiply the loss, at 60 cycles, 10,000 gausses, by the factor shown in the table. Values are most accurate for about a 4 per cent silicon steel, but are reasonably exact for lower silicon steels and may be used to give reasonably approximate values for Hipernik.

NOTE: To find the approximate iron loss at any induction or frequency, multiply the loss, at 60 cycles, 10,000 gausses, by the factor shown in the table. Values are most accurate for about a 4 per cent silicon steel, but are reasonably exact for lower silicon steels and may be used to give reasonably approximate values for Hipernik.

density permeabilities, will vary over a considerably greater range than the permeabilities at high values of magnetizing force.

Although electrical sheets are usually marketed under the trade names of the various manufacturers, the number of grades and the loss characteristics of these grades have been fairly well standardized (the "radio" grades are essentially the same as the standard). Accordingly, the figure corresponding to the 29 gage (0.014″) iron loss, expressed in watts per pound when tested at 10,000 gausses and 60 cycles, has been used to designate the grade of electrical sheet material.

Table 4. Loss in Watts per Pound of Electrical Sheets as a Function of Gage Commercial Grades in Common Use

The grade is designated by the guaranteed maximum iron loss when tested at 10,000 gausses, 60 cycles, A.S.T.M. method.

Data from Westinghouse Electric tests.
Ring samples, no air gaps.
60 cycle a-c tests with no air gaps have checked these figures closely.

The thickness of electrical sheets is ordinarily given in terms of the U. S. Standard sheet gage (see Sect. 1). For magnetic sheet of low silicon content (2 per cent and less) the table of sheet-iron gages and weights should be used. For material of medium- and high-silicon grades (above 2 per cent) the gage dimensions in the sheet-iron table are satisfactory, but the weights will be somewhat less. The approximate weight can be obtained by using the sheet-iron figures multiplied by a correction factor of 0.975.

17. RETENTIVE MATERIALS

General Considerations

The magnetic properties and the application of the various retentive or permanent magnet materials depend, in the main, on four factors, namely: (1) the physical dimen-

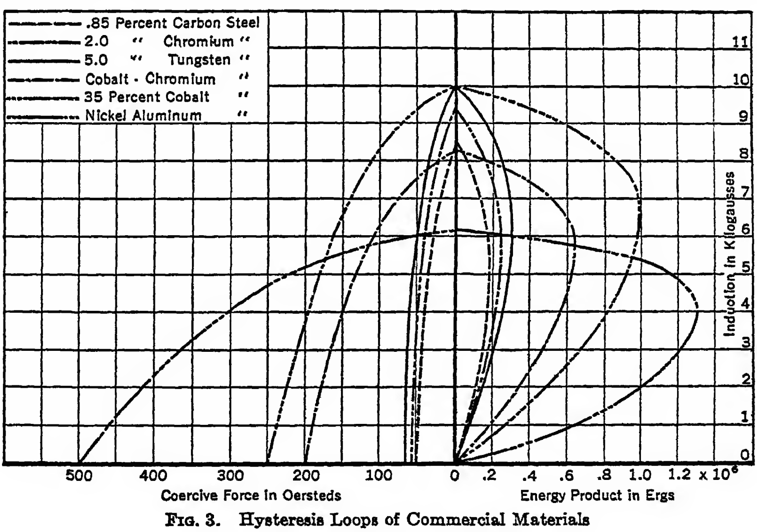

Fig. 3. Hysteresis Loops of Commercial Materials

sions of the magnetic circuit, (2) the heat treatment of the material, (3) the subsequent "stabilization," and (4) small variations in composition.

1. The relative lengths of the retentive material, of the air gap, and, if present, of the non-retentive material, together with cost and weight or size considerations, will determine, in general, the choice of magnetic material. When the air gap must be relatively large, or when weight or size are important considerations, materials having high coercive force will be used.

2. The desired magnetic properties of these materials are not developed, as a rule, until a final heat treatment has been given. Usually, precautions must be taken to avoid cracking, excessive oxidation, decarburization, or overheating; the temperatures must be rather closely controlled; and it is ordinarily desirable to keep these materials at high

temperatures as short a time as is practicable. Permanent magnet materials are ordinarily quite difficult to forge or machine.

3. After the material has been heat-treated and magnetized it is frequently necessary to put it in such condition that very little or no further change in magnetic properties will occur. This may be accomplished, but only by sacrificing a part of the initially available magnetic energy, by one or all of three methods: (*a*) prolonged "aging" at a slightly elevated temperature, usually about 100 deg cent for about 10 hours; (*b*) subjecting the material to mechanical shock or vibration, as by dropping it several feet to a hard surface; (*c*) applying a small negative, or alternating, demagnetizing force, as by introducing a slightly larger air gap than will later be used in the magnetic circuit.

4. Small amounts of various impurities will sometimes produce changes in the magnetic properties of retentive materials. Small percentages of sulfur, phosphorus, or oxygen are believed harmful, and loss of carbon in heat treatment may damage some grades considerably.

Data on Commercial Materials

1. Hysteresis loops are shown in Fig. 3.
2. General data on permanent magnet materials are shown in Table 7.

Maximum magnetic energy per unit cost	1.8	2.3	1.5	0.65	0.52	4.2

[a] Cooled in air.
[b] Cannot be forged or machined, may be ground, and casts fairly well.
[c] Heat to 1200 deg cent, quench, and age 4 hr at 700 deg cent.
[d] Annealing impairs the magnetic properties of this material and should be avoided. If necessary for machining, hold at 830 deg cent for 1 hr, cool 30 deg cent per hr to 600 deg cent, cool in air.
[e] Carbon fairly critical.
[f] The manganese is not essential, but increases the coercive force from 350 to 500, and lowers the residual induction from 7500 to 6000.
[g] Heat rapidly to 1160 deg cent, cool in air, heat slowly to 725 deg cent, cool in air, heat to 1000 deg cent, cool in moving air to 300 deg cent, and quench in oil, according to Darwins, Ltd., Sheffield, England.

18. SPECIAL MAGNETIC MATERIALS

LOW-INDUCTION MATERIALS. There are several magnetic materials which have remarkable magnetic characteristics at very low flux densities. These materials include those known as (1) "Conpernik" and (2) "Perminvar."

1. Conpernik is characterized by a constant permeability of a little over 1000 at flux densities up to several hundred gausses, and by very low hysteresis loss at these low inductions. The composition of Conpernik is the same as that of Hipernik, and the unusual properties are secured by a low temperature heat treatment. The hysteresis loss of Conpernik is about 1.6×10^{-2} erg per cc per cycle at an induction of 100 gausses. The material may be used to advantage in several ways, for example, in producing reactors with a reactance to resistance ratio well over 150, at frequencies of about 500 cycles. In order to keep eddy current losses low, it is usually used in 0.005-in. thickness.

2. Perminvar is characterized by somewhat similar properties, and is an alloy of iron, nickel, and cobalt, in one of several proportions. The magnetic properties are developed by special heat treatment.

HIGH-INDUCTION MATERIALS. An alloy of iron and cobalt, preferably in the ratio of 65 per cent iron to 35 per cent cobalt, has remarkable properties at very high inductions. The saturation induction is about 12 per cent higher than that of pure iron, or a little over 24,000 gausses; and at magnetizing forces between 50 and 200 oersteds the inductions are about 25 per cent higher than for iron. The material is used only for special applications because of its relatively high cost.

TEMPERATURE EFFECTS. 1. Alloys of copper and nickel, in the proportions of 70 per cent copper to 30 per cent nickel, with the addition of small amounts of manganese and silicon, and alloys of iron and nickel in the ratio 3 to 1 respectively, will show substantial and approximately linear changes in permeability with temperature, and are used as shunts for compensating the magnetic circuits of electrical instruments for changes in temperature.

2. An alloy of iron and nickel, with about 35 per cent nickel (Invar composition), will become non-magnetic at a slightly elevated temperature and is used in magnetic-thermal relays.

HIGH-FREQUENCY MATERIALS. For data on magnetic materials at high frequency see bibliography and Volume V, Section 2.

BIBLIOGRAPHY

The Properties and Testing of Magnetic Materials, by T. Spooner, published by McGraw-Hill, contains a great deal of practical information on commercial magnetic materials, and their application, and a very complete bibliography. Other works on the subject are Pender, H., Electricity and Magnetism for Engineers; Karapetoff, V., The Magnetic Circuit; Ewing, J. A., Magnetic Induction in Iron and Other Metals; Williams, S. R., Magnetic Phenomena; and The International Critical Tables, Vol. VI.

THERMAL PROPERTIES OF MATERIALS

19. THERMAL CAPACITY AND SPECIFIC HEAT

The thermal capacity of a body is defined as the heat absorbed by the body per unit increase in its temperature, there being during this change in temperature no change of state (e.g., no change from solid to liquid or from liquid to gaseous form or no chemical change) and no transfer of heat energy from the body in question to other bodies. The thermal capacity *per unit mass* of a substance is approximately constant, but increases slightly with increase in temperature; in the case of iron the increase with temperature is quite marked. Calling C the thermal capacity per unit mass of a substance, the heat absorbed by a homogeneous mass M when its temperature increases from t_1 to t_2 is

$$H = CM\,(t_2 - t_1) \tag{1}$$

provided C is constant.

The mean thermal capacity per unit mass of water (between 0 and 100 deg cent), when expressed in mean gram-calories per gram per degree centigrade, is numerically equal to unity. The ratio of the thermal capacity per unit mass of any substance to the mean thermal capacity of water is called the specific heat of the substance. The specific heat of a substance does not depend upon the units in which the various quantities are measured; its thermal capacity per unit mass does. When heat is expressed in mean gram-calories, mass in grams and temperature in degrees centigrade, the thermal capacity per unit mass is equal to its specific heat; compare with density and specific gravity.

CALCULATION OF HEAT ABSORBED OR GIVEN OUT.

C = specific heat (gram-calories per gram per degree centigrade),
M = mass heated,
$t_2 - t_1$ = rise of temperature.

Then for any set of units the heat absorbed is

$$H = kCM\,(t_2 - t_1) \tag{2}$$

where k has the following values:

Values of k

Unit of Heat or Energy	Unit of Mass	Temperature Scale	Value of k
Gram-calorie	Gram	Centigrade	1.000
Kilogram-calorie	Kilogram	Centigrade	1.000
Btu	Pound	Centigrade	1.800
Btu	Pound	Fahrenheit	1.000
Watt-second (joule)	Gram	Centigrade	4.183
Watt-second (joule)	Pound	Fahrenheit	1054
Kilowatt-hour	Kilogram	Centigrade	1.162×10^{-3}
Kilowatt-hour	Pound	Fahrenheit	2.928×10^{-4}

VALUES OF SPECIFIC HEAT. In the table below are given the values of the specific heat for the more common substances used in engineering work. These numbers, are also equal to the thermal capacity per unit mass, when mass is expressed in grams, temperature in degrees centigrade, and heat in gram-calories.

International Critical Tables.

by a considerable absorption of heat. The temperature at which the change takes place is called the melting point or freezing point (the reverse change takes place at the same

temperature), and the heat absorbed per unit mass is called the heat of fusion or heat of liquefaction; this same amount of heat is given out when the body solidifies. Many substances, however, have no definite melting point, the change from one state to the other being gradual; such substances begin to melt at a lower temperature than that at which solidification begins during cooling. The melting points and heats of fusion for some common substances are given in Table 2.

21. TRANSFER OF HEAT

When a body is at a higher temperature than the surrounding bodies, energy is transferred from the hotter to the colder bodies, as is manifested by the changes in temperature or state which tend to, or actually do, take place, even though the intervening space is entirely void of matter. The energy thus transferred from one body to another through empty space is called radiant energy or radiant heat, and is similar in nature to the energy radiated in the form of light waves and electromagnetic waves. The waves of radiant heat have a length greater than that of light waves and less than that of the ordinary electromagnetic waves used in wireless telegraphy. Radiant heat is absorbed by, transmitted through and reflected by, ordinary matter in much the same way that light waves are absorbed, transmitted and reflected. Matter which is transparent to light waves, however, may be practically opaque to heat waves; e.g., water absorbs practically all the heat waves which fall upon it.

When a hot and a cold body are separated by a fluid which is free to circulate, heat is transferred from the hot to the cold body by currents of the fluid itself flowing from one to the other; similarly, all parts of a fluid which is being heated quickly come to approximately the same temperature. This transfer of heat by currents of the fluid itself is called convection.

In the case of a hot and a cold body separated by a solid the transfer of heat, which may be very rapid, particularly when the separating medium is a metal, is probably due to an extremely rapid to-and-fro motion of the molecules which constitute the medium. In any event, the process is essentially different from the transfer of heat either by radiation or by convection; it is described by the term *conduction* of heat. In a fluid heat is transferred both by conduction and convection.

RADIATION, ABSORPTION, AND REFLECTION OF HEAT. The rate at which a hotter body radiates heat, and a colder body absorbs heat, depends upon the state of the surfaces of the bodies as well as on their temperatures. The rate of radiation and of absorption are increased by darkness and roughness of the surfaces of the bodies, and diminished by smoothness and polish. For this reason the covering of steam pipes and boilers should be smooth and of a light color; uncovered pipes and steam-cylinder covers should be polished.

The heat radiated by a body at a given temperature T to surrounding bodies at a lower temperature is equal to the heat which this body would absorb at this same temperature T from surrounding bodies at a higher temperature. When a given quantity of radiant heat strikes a body, only part of the heat is, as a rule, absorbed, the rest being reflected.

Let H_i be the incident heat, H_r the reflected heat, and H_a the absorbed heat, at temperature t, and let H_e be the heat which the body would emit at this same temperature to bodies at a lower temperature; then

$$H_i = H_r + H_a$$
$$H_a = H_e$$

DEFINITION OF "BLACK BODY"; STEFAN-BOLTZMANN LAW. A "black body" is defined as one that absorbs all radiations falling upon it, neither reflecting nor transmitting any. The radiation of such a body is a function of the temperature alone, and is identical with the radiation inside an inclosure all parts of which have the same temperature. By heating the walls of an inclosure as uniformly as possible and observing the radiation through a very small opening, a practical realization of a black body is obtained.

RADIATING AND REFLECTING POWERS. The ratio of the heat radiated per unit area by any surface at a given temperature T to the heat radiated per unit area by an absolutely black surface at this same temperature T is called the radiating power, or relative emissivity, of the surface at that temperature. The difference between this ratio and unity is a measure of the heat which would be reflected by this surface at the same temperature, and is defined as the reflecting power of the surface. The radiating power of a surface depends upon the temperature of the surface; at very high temperatures the radiating power of every surface approaches the value of unity, i.e., at high tempera-

tures the total energy radiated by any surface approaches in value the total energy radiated by an absolutely black body. Table 3, taken in part from Kent's Mechanical Engineer's Pocketbook and in part from Langmuir's paper (*Trans. A.I.E.E.*, 1913), gives the approximate value of the radiating power of some common surfaces at ordinary temperatures.

Oiling a polished surface may increase its radiating power from 2 to 3 times, but oiling does not seriously affect the radiating power of a rough surface.

CONDUCTION OF HEAT. Whenever a difference of temperature is maintained between any two parts of the same body there is a transfer of heat from the hotter to the colder part by the process described by the term conduction, as distinguished from radiation and convection.

Table 3. Approximate Radiating and Absorbing Powers

Surface	Radiating or Absorbing Power	Surface	Radiating or Absorbing Power
Lamp black	1.00	Zinc, polished	0.19

Aluminum paint on cast iron	0.47	Monel metal, polished	0.40
Gold enamel on cast iron	0.39	Monel metal, oxidized	0.44
Mercury, about	0.23	Gold, plated	0.05
Wrought iron, polished	0.23	Gold on polished steel	0.03
		Silver, polished bright	0.03

Consider a flat layer *within* a substance, the two sides of the layer being parallel and its thickness small compared with its area. Let one side of this be maintained at a constant temperature T, the same at all points of this surface, and the other side of the layer be maintained at a constant temperature T_1; let A be the area of the layer (i.e., of one of its flat surfaces) and x the thickness of the layer. Then the amount of heat transferred through the layer in time t is

$$H = \frac{K A (T - T_1)t}{x} \tag{3}$$

where K, called the thermal conductivity, is approximately a constant for a given material, and is independent of the temperature difference $T - T_1$, when this difference is small; K is not constant, however, for wide temperature variations, particularly in the cases of gases (see paragraph following Table 5). Values of K are given in Tables 4 and 5. The reciprocal of the thermal conductivity, viz., $\rho = 1/K$, is called the thermal resistivity.

The values of K given in the tables below are the values of this factor when H is expressed in gram-calories, A in square centimeters, x in centimeters, $(T - T_1)$ in degree centigrade, and t in seconds; i.e., K is the number of gram-calories transmitted per second through a cube 1 cm on each edge when a difference of temperature of 1 deg cent is

Unit of Heat	Unit of Area	Unit of Thickness	Unit of Time	Unit of Temp. Diff.	Multiply K by
Gram-calorie	sq cm	cm	second	°C	1.000
Kg-calorie	sq m	cm	hour	°C	3.600×10^4
Btu	sq ft	inch	hour	°F	2902
Watt-seconds	sq cm	cm	second	°C	4.183
Watt-seconds	sq ft	inch	second	°F	850.8
Kwhr	sq m	cm	hour	°C	41.83
Kwhr	sq ft	inch	hour	°F	0.8508

maintained between opposite faces of this cube. For other units the value of K as given should be multiplied by the factor noted in the table above.

TEMPERATURE COEFFICIENT OF THERMAL CONDUCTIVITY. For metals the variation of the internal thermal conductivity with temperature may be expressed with a fair degree of approximation by the relation

$$K = K_0 (1 + at) \tag{4}$$

where K_0 is the conductivity at 0 deg cent, say, and K is the conductivity at any other temperature of t deg cent, and a is a constant. The coefficient a may be either positive or negative; its value for some of the common metals is given in Table IV.

VALUES OF THERMAL CONDUCTIVITY (K) OF MATERIALS. In the following tables, 4 and 5, are given the thermal conductivities of certain common non-metallic and metallic substances respectively. The data are from the following sources: Landolt-Börnstein, Physikalish-Chemische Tabellen, 1923; Randolph, C. P., *Trans. Am. Electrochem. Soc.*, 1912; Smithsonian Physical Tables, 1920; Langmuir, *A.I.E.E.*, *Trans.*, 32, p. 301, February, 1913; International Critical Tables, Vol. V, 1929.

THERMAL CONDUCTIVITY OF LAMINATED STEEL. The thermal conductivity of a laminated iron core perpendicular to the laminations depends upon the conductivity of the iron and the oxide scale or varnish on the laminations and also upon the pressure on the laminations. G. E. Luke (*Elec. World*, 70, p. 562, Sept. 22, 1917) gives the following values for K in gram-calories per cm³ per deg cent.

Material	Pressure, pounds per square inch			
	25	50	75	100
Silicon steel, 15.5 mils thick, 3 per cent oxide layer..........................	0.00096	0.00115	0.00125	0.00132
Ordinary varnished steel, 18.35 mils thick, 5 per cent varnish layer.......	0.00094	0.00098	0.00109	0.00120

THERMAL CONDUCTIVITY OF GASES. The thermal conductivity of a gas depends not only upon the nature of the gas but also upon its specific heat at constant volume, C_v, and its absolute temperature T. Langmuir (*Phys. Rev.*, 34, p. 408, 1912) gives the following values for the *watts* conducted from a plane surface through an adhering film A square centimeters in area and B centimeters thick.

$$W = \frac{A}{B} (\phi_2 - \phi_1) \tag{5}$$

where ϕ_1 and ϕ_2 are functions of the absolute temperatures at the two surfaces of the film, as given in the following table:

Values of ϕ

§ See also paragraph Thermal Conductivity of Laminated Steel on page 2–54.

dimensions continue long after it has attained the same uniform temperature throughout. This effect, which is particularly marked in glass, is known as thermal hysteresis. It can be largely eliminated by prolonged heating at a high temperature followed by a very gradual cooling, i.e., by annealing.

COEFFICIENT OF EXPANSION OF GASES. Gases present a remarkable uniformity, all the so-called permanent gases expanding about $^1/_{273}$ part of their *initial volume at 0* deg cent per degree centigrade increase of temperature, irrespective of the pressure, provided this remains constant throughout. That is, for any of the ordinary gases,

$$V = V_0\left(1 + \frac{t_c}{273}\right)$$

where V_0 is the volume at 0 deg cent, and V the volume at any other temperature t_c deg cent, the pressure being the same at both temperatures. If the temperature is expressed in fahrenheit degrees and V_0 is the volume at 0 deg fahr, then

$$V = V_0\left(1 + \frac{t_f}{460}\right)$$

Note that −273 and −460 are the absolute zeros on the centigrade and fahrenheit scales respectively.

Table 6. Conductances of Various Thicknesses of Insulations Computed from Conductivities per Inch of Thickness

Mercury (− 10 to 300 deg cent.):

$$V = V_0 (1 + 1.805553 \times 10^{-4}\, t + 1.2444 \times 10^{-8}\, t^2 + 2.539 \times 10^{-11}\, t^3)$$

24. FLASH POINT OF OILS

The flash point of an oil is the temperature to which the oil must be raised before the vapor immediately above it will take fire upon the application of a flame. This temperature depends to an appreciable extent upon the size of the flame, the method of applying it, and the shape and dimensions of the containing vessel. The following values of the flash point for various oils are taken from J. Lewkowitisch, Chemical Technology and Analysis of Oils, Fats and Waxes.

Table 9. Flash Point of Oils

Oils	Spec. Grav. at 60° F	Flash Point, ° F
Mineral oils:		
Refined American	0.875 to 0.920	325 to 425
Refined Russian	0.895 to 0.915	300 to 425
Scotch	0.875 to 0.895	300 to 350
Natural (dark) American	0.880 to 0.895	325 to 425
Natural (dark) Russian	0.910 to 0.915	250 to 300
Natural filtered American	0.885 to 0.905	450 to 575
Animal oils:		
Sperm	0.8804 to 0.8807	446 to 457
Lard	0.9172	494
Tallow	0.951	265
Neat's foot	0.9178	470
White whale	0.9207	476
Vegetable oils:		
Castor	0.963	275
Linseed	0.930	285
Olive	0.914	305
Rape, crude	0.920	265
Rape, refined	0.911	305

ELECTRIC CIRCUITS AND ELECTRIC LINES

By Irven Travis

ALTERNATING CURRENTS

The definitions given below are applicable to currents, electromotive forces, potential differences, or any other function of time. These definitions are those recommended by the Sectional Committee on Electrical Definitions of the A.I.E.E.

1. GENERAL DEFINITIONS, PERIODIC QUANTITIES

(*a*) An *oscillating quantity* is a quantity which as a function of some independent variable (such as time) alternately increases and decreases in value, always remaining within finite limits.

(*b*) A *periodic quantity* is an oscillating quantity the values of which recur for equal increments of the independent variable.

(*c*) The *period* of a periodic quantity is the smallest value of the increment of the independent variable which separates recurring values of the quantity.

(*d*) A *cycle* is the complete series of values of a periodic quantity which occur during a period.

(*e*) The *frequency* of a periodic quantity in which time is the independent variable is the reciprocal of the period.

(*f*) The *angular velocity* of a periodic quantity is the frequency multiplied by 2π.

(*g*) An *alternating quantity* is a periodic quantity which has alternately positive and negative values.

In order to avoid repetition the following statements will be given in terms of electric currents; they apply equally well to electromotive forces, drops of potential, etc.

If a given current is represented by the equation

$$i = f(t) \tag{1}$$

and if the function $f(t)$ has the property that

$$f(t) = f(t + T) \tag{2}$$

in which T is a constant, then the current is said to be periodic in time and T is the period. If time is measured in seconds, then $1/T$ represents the number of periods per second and is usually denoted by f. The frequency f may also be said to be the number of cycles per second. If, as often happens, the current is expressible more simply as

$$i = f(\omega t) \tag{3}$$

in which ω is defined by

$$f(\omega t) = f(\omega t + 2\pi) \tag{4}$$

then the constant ω, being equal to 2π divided by the period or 2π times the frequency, is the angular velocity as defined in (*f*). That is

$$\omega = 2\pi f = \frac{2\pi}{T} \tag{5}$$

2. MAXIMUM, AVERAGE, AND RMS OR EFFECTIVE VALUES

The *instantaneous value* of an alternating current is the value of the current at any instant. Instantaneous values of current, potential difference, and electromotive force will be designated by lower-case letters throughout this section, viz., i, v, and e, respectively.

The *maximum value* of an alternating current is the numerical value of its maximum instantaneous value. Maximum values will be designated by capital letters with the subscript m.

The *half-period average value* of a symmetrical alternating current * is the absolute

*A symmetrical alternating quantity is one of which all values separated by a half-period have the same magnitude but opposite sign. The term half-period average has no meaning for alternating currents which are not symmetrical.

value of the algebraic average of the values of the current taken throughout a half period, beginning with a zero value. If the current has more than two zeros during a cycle, that zero shall be taken which gives the largest half-period average value. The expression for the half-period average of a symmetrical alternating current $i(t)$ having a period T is

$$I_{av} = \frac{2}{T}\int_{t_0}^{t_0+\frac{1}{2}T} i(t)\,dt \tag{6}$$

where t_0 is chosen such that $i(t) = 0$ at t_0, and I_{av} is the largest value obtainable.

The square root of the means of the squares of the instantaneous values of an alternating current over a complete period is called the rms, or the *effective* value of the alternating current. In specifying the value of an alternating current as so many amperes this rms value is always meant unless specifically stated otherwise. In the same manner the square root of the mean of the squares of the instantaneous values of an alternating potential difference over a complete period is called the rms value of the alternating potential difference. When the value of an alternating potential difference is specified as so many volts, this rms value is always meant unless specifically stated otherwise.

The reason for selecting this particular function of the instantaneous values of an alternating current or a potential difference as a measure of the current or the potential difference is that the deflection of all instruments used in alternating-current measurements is a function of this rms value. (See Measurements.) Moreover, the average power dissipated as heat in a resistance, r, when an alternating current of rms value I flows through it, is rI^2.

Rms values will be designated throughout this section by capital letters without subscripts.

The general expression for the rms value of an alternating current is

$$I = \sqrt{\frac{1}{T}\int_0^T i^2\,dt} \tag{7}$$

and similarly for an alternating potential difference.

3. FORM FACTOR, CREST OR PEAK FACTOR, DEFORMATION FACTOR

The *form factor* of a symmetrical alternating current is the ratio of the effective value of the current to its half-period average value.

The *peak* or *crest factor* of an alternating current is the ratio of the maximum value of the current to its effective value; this is also called the *amplitude factor*.

The *equivalent sinusoidal current* of a given alternating current is a sinusoid having the same period and the same effective value of the given alternating current.

The *deformation factor* of an alternating current is the ratio to the maximum value of the equivalent sinusoidal current *of* the maximum difference between the corresponding values of the current considered and the equivalent sinusoid, when the two are superimposed in such a way as to make this difference a minimum.

4. POWER, POWER FACTOR, VOLT AMPERES, REACTIVE POWER

Let v be the value at any instant of the potential drop from any point 1 to any other point 2, and let i be the instantaneous value of the current from 1 to 2 at this same instant; then the *power input* at this instant is

$$p = vi \tag{8}$$

When v and i are both positive (i.e., in the direction from 1 to 2, say) or when they are both negative, the power input is positive, but when v is positive and i negative, or vice versa, the power input is negative, i.e., there is an actual power output.

The average value of the product vi over a complete period for both v and i (or over any whole number of periods) is the *average power* input or output, usually called simply the power input or output (input when the average of vi is positive, output when the average of vi is negative), the word average being understood. That is, the average power input is

$$P = \frac{1}{T}\int_0^T p\,dt = \frac{1}{T}\int_0^T vi\,dt \tag{9}$$

T being a complete period. For the actual measurement of alternating-current power see Section 5, Measurements.

Only in certain special cases (see below) is the average power input P equal to the product of the rms value V of the potential difference by the rms value I of the current; it can never be greater and as a rule is less. The ratio of the average power P to the product of the rms value V of the potential difference by the rms value I of the current is called the *power factor* of the circuit between the terminals considered, i.e.,

$$\text{Power factor} = \frac{P}{VI} \tag{10}$$

When V is expressed in volts and I in amperes, then P must be in watts; when V is expressed in kilovolts and I in amperes, P must be in kilowatts.

The product of the rms volts across the terminals of a circuit and the rms amperes through it is called the *volt-amperes* or *apparent power* taken by the circuit; this product divided by 1000 is called the kilovolt-ampere input. Or, when V is in volts and I in amperes,

$$\text{Volt-amperes} = VI \tag{11}$$

$$\text{Kilovolt-amperes} = \frac{VI}{1000} \tag{11a}$$

Kilovolt-amperes is usually abbreviated kva, kv-a, or K.V.A., the first form being that recommended by the American Institute of Electrical Engineers and used in this book.

Reactive power has no accepted definition when either the current or emf is non-sinusoidal. (See below.)

5. SINUSOIDAL CURRENTS AND VOLTAGES, PHASE ANGLE

A *simple sinusoidal current* (simple harmonic current) is an alternating current the instantaneous values of which are equal to the product of a constant and the sine of an angle having values varying linearly with time. Thus

$$i = I_m \sin(\omega t + \theta) \tag{12}$$

where t represents time in seconds, measured from any arbitrarily chosen instant; I_m the maximum value of the current; $\omega = 2\pi f = 2\pi/T$, where f is the frequency in cycles per second and T the period as a fraction of a second; and θ a constant which depends upon the instant chosen as the zero of time.

The quantity I_m is often called the *amplitude* of the sinusoidal current.

The ratio of I_m to the rms value I (the amplitude factor) for a sinusoidal current is $\sqrt{2}$.

The *phase* of a periodic current, for a particular value of the independent variable, is the fractional part of a period through which the independent variable has advanced measured from an arbitrary origin. In the case of a simple sinusoidal current, the origin is usually taken as the last previous passage through zero from the negative to positive direction. The *phase angle* is the angle obtained by multiplying the phase by 2π if the angle is to be expressed in radians, or by 360 deg if the angle is to be expressed in degrees.

The phase angle is thus equal to $(\omega t + \theta)$. In electric circuit theory the phase differences between various quantities having the same frequency are of importance. Since these differences in phase are independent of the instant at which they are evaluated, it is customary to refer to the angle θ (which is the phase angle when $t = 0$) as the phase angle of the current given by eq. (12).

In general, when a sine-wave electromotive force is impressed on a circuit the resulting current is likewise a sine function of time after a very brief interval, (see Handbook of Engineering Fundamentals, Eshbach, John Wiley & Sons, " Transients ") having the same frequency, but the emf and current do not reach their maximum values simultaneously. Let the current be represented by eq. (12) and let the voltage be given by

$$v = V_m \sin \omega t \tag{12a}$$

where t is the time measured from the instant when $v = 0$ and is increasing in the positive direction. The voltage reaches its maximum value when $t = \dfrac{\pi}{2\omega}$, while the current reaches its maximum value when $t = \dfrac{\pi}{2\omega} - \dfrac{\theta}{\omega}$. Hence when θ is positive the voltage reaches its maximum value θ/ω seconds after the current reaches its maximum, or the current reaches its maximum value θ/ω seconds before the voltage reaches its maximum; when θ is negative the current reaches its maximum value θ/ω seconds after the voltage reaches its maximum. In the first case the current is said to " lead " the voltage and in the second case the current is said to " lag " the voltage. The angle θ is called the angular phase difference between the current and voltage.

When the phase difference is zero the current and voltage are said to be "in phase;" when the phase difference is $\pi/2$ radians or 90 deg the current and voltage are said to be "in quadrature;" when the phase difference is π radians or 180 deg the current and voltage are said to be "in opposition."

6. POWER AND POWER FACTOR FOR SINUSOIDAL CURRENT AND VOLTAGE

Let the voltage drop from terminal 1 to terminal 2 through any piece of apparatus be $v = \sqrt{2}V \sin(\omega t + \theta_v)$, and the current from terminal 1 to terminal 2 be $i = \sqrt{2}I \sin(\omega t + \theta_i)$, where V and I are the rms values and therefore $\sqrt{2}V$ and $\sqrt{2}I$ are the maximum values. Then the instantaneous power input is

$$p = vi = VI[\cos(\theta_v - \theta_i) - \cos(2\omega t + \theta_v + \theta_i)] \tag{13}$$

A study of Fig. 1 will show the physical meaning of this expression. The average power input is

$$P = VI \cos(\theta_v - \theta_i) \tag{13a}$$

where $(\theta_v - \theta_i)$ is the angular difference in phase between the current and voltage. Putting θ for this difference in phase, viz., $\theta = \theta_v - \theta_i$, eq. (13a) may be written

$$P = VI \cos\theta \tag{13b}$$

Whence the power factor of the load supplied to the apparatus is, from eq. (10),

$$\cos\theta = \frac{P}{VI} \tag{14}$$

Since in the case of sine-wave currents and voltages the power factor is equal to the cosine of the angle which expresses the difference in phase between them, this difference in phase is frequently called the "power-factor angle." When the wave shape is not a pure sine curve, the power factor cannot be interpreted as the cosine of the phase difference, for phase difference has no definite meaning except in reference to sine waves; see definitions above. A non-sinusoidal voltage and current may both reach their zero values at the same instant, and in a sense may be said to be "in phase," but the power factor as defined by eq. (10) may be far from unity.

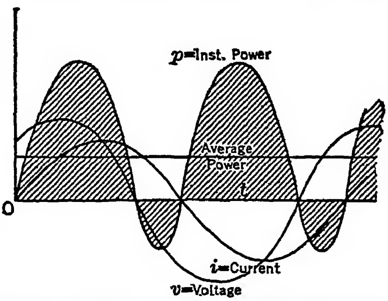

FIG. 1. Power *versus* Time in the Case of a Sinusoidal Current and Voltage

The *reactive power* in a circuit in which a sinusoidal current is flowing is equal to the effective emf times the effective current times the sine of the phase difference between them. When the emf and current are in volts and amperes respectively the reactive power is in *vars*.

7. VECTOR REPRESENTATION OF SINUSOIDS

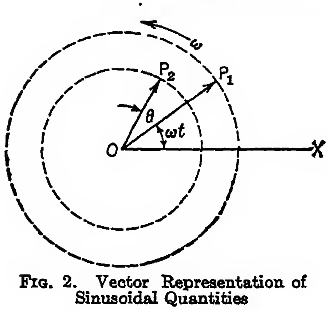

FIG. 2. Vector Representation of Sinusoidal Quantities

Consider any sine function

$$i = I_m \sin \omega t$$

The value of i at any instant may be represented graphically, see Fig. 2, by the vertical projection (i.e., the vertical distance from P_1 to OX) of a point P_1 at the end of a radius $OP_1 = I_m$ which revolves* at a constant angular velocity ω about a fixed point O, the angle ωt being measured from the horizontal fixed line OX. Similarly, any other sine function

$$v = V_m \sin(\omega t + \theta)$$

may be represented by the vertical projection of the point P_2 at the end of a radius $OP_2 = V_m$ also revolving about O with a constant angular velocity ω, the angle between OP_1 and OP_2, when the fre-

* Counter-clockwise rotation has been adopted (1911) as standard by the International Electrotechnical Commission.

quency of both i and v is the same, remaining fixed in value and equal to the difference in phase θ between v and i. That is, v and i may be represented by rotating vectors. When v and i are of the same frequency the relative position of the two vectors remains fixed. Similarly any number of currents and voltages of the same frequency may be represented by rotating vectors which remain fixed with respect to one another.

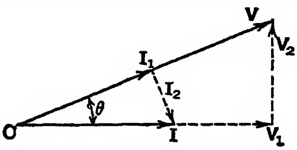

FIG. 3. Components of Vectors

Instead of referring the various rotating vectors to a fixed line OX, this line of reference may also be considered as rotating with the same speed as the various vectors, or any one of the vectors may be chosen as the line of reference, for example, the vector OP_1 in Fig. 2. The rotating vectors referred to this rotating line of reference are then fixed with respect to this line of reference, and the entire diagram may be considered as fixed, as in Fig. 3.

Instead of making the vectors equal in length to the maximum values of the sine functions they may be chosen equal in length to their rms values. This merely introduces a factor $\sqrt{2}$ so that the instantaneous value of the quantity which any rotating vector is considered to represent is equal to $\sqrt{2}$ times the perpendicular distance from the end of the vector to the fixed line of reference.

Since the rms values and phase relations of sine-wave currents and voltages may be represented by vectors, sine-wave currents may be added in exactly the same manner as vectors, or forces, are added, and similarly for sine-wave voltages. To add any two sine-wave currents or voltages not only must their effective values be known but also their phase relation; the resultant of two alternating voltages of rms values V_1 and V_2 is never the arithmetical sum of V_1 and V_2, except when the two voltages are exactly in phase, and similarly for alternating currents.

In Fig. 3, considering OI as equal to the rms value I of the current and OV as representing the rms value V of the voltage, the voltage V may be considered as made up of two components, viz.: $V_1 = V \cos\theta$ in phase with I, $V_2 = V \sin\theta$ in quadrature with I. The average power corresponding to the component $V_1 = V\cos\theta$ is, from eq. (13b), $V_1 I = VI\cos\theta$, and is equal to the total power corresponding to V and I. The average power corresponding to the component $V_2 = V\sin\theta$, since the angle between the current and this component of the voltage is 90 deg, is equal to zero. The voltage component $V_1 = V\cos\theta$ is therefore frequently called the "power" component of the voltage, and the component $V_2 = V\sin\theta$ is frequently called the "wattless" component of the voltage. These terms, however, are not recommended. It is preferable to refer to these two components as the in-phase and quadrature components, respectively. The terms active and reactive components are also used.

Similarly, the current I may be considered as made up of two components, viz.:

$$I_1 = I\cos\theta \text{ in phase with } V$$

$$I_2 = I\sin\theta \text{ in quadrature with } V$$

The first component is called the in-phase component of the current, and the second the quadrature component of the current.

8. FOURIER SERIES, HARMONICS

It can be shown that any single-valued, periodic function (which fulfils certain mathematical conditions always fulfilled by electric currents) may be represented by a sum of sinusoids of which the frequencies form an arithmetical progression. Hence any current $i(t)$ can be written

$$\left.\begin{aligned} i(t) &= A_1 \sin 2\pi\frac{t}{T} + A_2 \sin 2\pi\frac{2t}{T} + \ldots + A_n \sin 2\pi\frac{nt}{T} + \ldots \\ &B_0 + B_1\cos 2\pi\frac{t}{T} + B_2\cos 2\pi\frac{2t}{T} + \ldots + B_n\cos 2\pi\frac{nt}{T} + \ldots \end{aligned}\right\} \tag{15}$$

where the values of the coefficients A and B are given by the integrals:

$$A_n = \frac{2}{T}\int_0^T i(t)\sin 2\pi\frac{nt}{T}\,dt \tag{15a}$$

$$B_n = \frac{2}{T}\int_0^T i(t)\cos 2\pi\frac{nt}{T}\,dt \tag{15b}$$

The series of eq. (15) is called a *Fourier series*.

If the terms involving the same frequencies are combined, and if $\frac{2\pi}{T} = \omega$, eq. (15) may be written

$$i(t) = I_0 + I_1 \sin(\omega t - \theta_1) + I_2 \sin(2\omega t - \theta_2) + \ldots + I_n \sin(n\omega t - \theta_n) + \ldots \quad (16)$$

The term $I_1 \sin(\omega t - \theta_1)$ is called the *fundamental*, and the terms $I_n \sin(n\omega t - \theta_n)$ are called *harmonics*. The *order* of a harmonic is the ratio of the harmonic frequency to the frequency of the fundamental. Each harmonic is characterized by two constants, its amplitude I_n and the angle θ_n. It should be noted that this angle may be given in either of two ways:

$$I_n \sin(n\omega t - \theta_n) \quad (16a)$$

$$I_n \sin n(\omega t - \theta'_n) \quad (16b)$$

In the first notation the angle θ_n is taken relative to the period of the harmonic, whereas in the second notation the angle θ'_n is taken relative to the period of the fundamental. It follows that

$$\theta_n = n\theta'_n \quad (16c)$$

The mathematical statement of the definition given above for a symmetrical alternating current is

$$i(\omega t + \pi) = -i(\omega t) \quad (17)$$

from which it follows by substitution of eq. (16) that

$$a_2 = a_4 = a_6 = \ldots = a_{2k} = \ldots = 0 \quad (18)$$

i.e., all the even harmonics of a symmetrical alternating current are zero.

If the two half-periods are alike and if, further, each is symmetrical about an axis erected at a quarter of a period from a null point then not only are the even harmonics zero but the θ's in eq. (16) are all either zero or π. In this case all the odd harmonics are in phase or in direct opposition. This type of symmetry often exists in commercial alternating currents. If this more restricted type of symmetry holds, the current may be written

$$i(t) = I_1 \sin \omega t + I_3 \sin 3\omega t + I_5 \sin 5\omega t + \ldots \quad (19)$$

or in terms of cosine functions,

$$i(t) = I_1 \cos \omega t + I_3 \cos 3\omega t + I_5 \cos 5\omega t + \ldots \quad (19a)$$

The odd harmonics may be divided into two groups, those of order $4k - 1$ and those of order $4k + 1$. Harmonics of the first class have the same sign in (19*a*) as in (19); those of the second class have opposite signs in (19) and (19*a*). Thus harmonics of order $4k - 1$ are in phase at their maximum values if they are in phase at their zero values; harmonics of order $4k + 1$ are in opposition at their maximum values if they are in phase at their zero values, and conversely. These facts are of importance in the consideration of harmonics in synchronous machines and induction motors.

If an analytic expression for $i(t)$ is available and if the integrations (15*a*) and (15*b*) can be performed, the terms of the Fourier series (15) can be written out. In practice the function $i(t)$ will usually be obtainable only in the form of a plotted curve and the evaluation of the A's and B's must be carried out by graphical means. This process is called *harmonic analysis*. Various means of harmonic analysis have been devised, the Fisher-Hinnen method being perhaps the most convenient in ordinary cases.

This method is quite simple when the wave contains only the fundamental and the third, fifth, and seventh harmonics. When even harmonics are present, or when higher odd harmonics than the seventh exist, certain corrections must be applied. Since voltage and current waves usually contain only odd harmonics, and seldom contain higher harmonics than the seventh, the simple method without corrections is usually sufficiently accurate.

WAVES CONTAINING ONLY THE THIRD, FIFTH, AND SEVENTH HARMONICS. To determine the nth harmonic (n equals 3, 5, or 7), divide the base of a half-wave into $2n$ equal parts and measure the ordinates of the wave at the beginning of each of these sections of the base. Call these ordinates $y_1, y_2, y_3 \ldots y_{2n}$, taking the y's positive if above the base line, negative if below. y_1 will be zero, since the first section begins where the resultant wave crosses the base line.

Then the ordinates of this harmonic at the points 1 and 2 are, respectively,

$$A_n = \frac{1}{n}[(y_5 + y_9 + \ldots y_{2n-1}) - (y_3 + y_7 + \ldots y_{2n-3})]$$

$$B_n = \frac{1}{n}[(y_2 + y_6 + \ldots y_{2n}) - (y_4 + y_8 + \ldots y_{2n-2})]$$

The maximum value of this harmonic is

$$Y_n = \sqrt{A_n^2 + B_n^2}$$

and the phase angle, calling the wavelength of the fundamental 360 deg, is

$$\phi_n = \frac{1}{n}\tan^{-1}\frac{A_n}{B_n}$$

These formulas give the third, fifth, and seventh harmonics (n = 3, 5, and 7, respectively). The fundamental is found by calculating

$$A_1 = -(A_3 + A_5 + A_7)$$
$$B_1 = y_0 + B_3 - B_5 + B_7$$

where y_0 is the mid-ordinate of the half-wave. Then

$$Y_1 = \sqrt{A_1^2 + B_1^2}$$
$$\phi_1 = \tan^{-1}\frac{A_1}{B_1}$$

The equation of the given wave is then

$$y = Y_1 \sin(x + \phi_1) + Y_3 \sin 3(x + \phi_3) + Y_5 \sin 5(x + \phi_5) + Y_7 \sin 7(x + \phi_7).$$

The *effective* value of the given wave is

$$Y = \sqrt{\frac{Y_1^2 + Y_3^2 + Y_5^2 + Y_7^2}{2}}$$

and the average value is

$$Y_{av} = \frac{2}{\pi}[Y_1 \cos\phi_1 + {}^1/_3\, Y_3 \cos 3\phi_3 + {}^1/_5\, Y_5 \cos 5\phi_5 + {}^1/_7\, Y_7 \cos 7\phi_7]$$

In using the above formulas strict attention must be paid to algebraic signs.

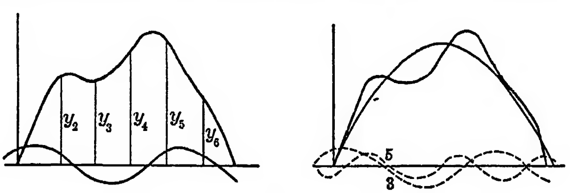

FIG. 4. Fisher-Hinnen Method of Wave Analysis

Example. Find the third harmonic in the wave shown in Fig. 4. The values of the six ordinates are found by measurement to be 0, 676, 660, 940, 1004, and 554, respectively. Then

$$A_3 = {}^1/_3(1004 - 660) = 114.7$$
$$B_3 = {}^1/_3(676 + 554 - 940) = 96.7$$
$$Y_3 = \sqrt{(114.7)^2 + (96.7)^2} = 150$$
$$\phi_3 = {}^1/_3 \tan^{-1}\frac{114.7}{96.7} = 16.6°$$

Similarly, for the fifth harmonic,

$$A_5 = -92.8 \text{ and } B_5 = 37.4$$
$$Y_5 = 100 \quad\text{and}\quad \phi_5 = -13.6°$$

For the fundamental

$$A_1 = -114.7 + 92.8 = -21.9$$
$$B_1 = 940 + 96.7 - 37.4 = 999.3$$
$$Y_1 = \sqrt{(21.9)^2 + (999.3)^2} = 1000$$
$$\phi_1 = \tan^{-1}\frac{-21.9}{999.3} = -1.25°$$

Hence the complete expression for the given wave, taking as the origin the point at which the resultant wave crosses the base line in the rising direction, is

$$y = 1000 \sin(x - 1.25°) + 150 \sin 3(x + 16.6°) + 100 \sin 5(x - 13.6°)$$

The *effective* value is then 718, and *average* value 673.

WAVES CONTAINING ANY NUMBER OF HARMONICS, ODD OR EVEN. See *Elec. J.*, 1908, Vol. 5, p. 386; *Electrotechm. Zeit.*, 1913, Vol. 34, p. 936.

9. RMS VALUE AND POWER OF NON-SINUSOIDAL CURRENTS

The rms value of a non-sinusoidal current can be obtained directly from eq. (3), or if the rms values I_1, I_2, I_3, etc., of the fundamental and harmonics are known the rms value of the resultant current is

$$I = \sqrt{I_1^2 + I_2^2 + I_3^2} + \ldots \tag{20}$$

A like relation holds for the rms value of a non-sinusoidal voltage. Similarly, if for example a 25-cycle emf, say E_{25}, and a direct emf, say E_d, are acting in series in the same circuit, the resultant emf of the combination is

$$E = \sqrt{E_{25}^2 + E_d^2} \tag{21}$$

The power corresponding to non-sinusoidal currents and voltages may be computed as follows:

Let I_1 be the rms value of the fundamental of the current, V_1 the rms value of the fundamental of the voltage, and θ_1 the difference in phase between these two fundamentals, both being of the same frequency; let I_2, V_2, and θ_2 be the corresponding quantities for the second harmonic; let I_3, V_3, and θ_3 be the corresponding values for the third harmonic, etc. Then the average power is

$$P = V_1 I_1 \cos\theta_1 + V_2 I_2 \cos\theta_2 + V_3 I_3 \cos\theta_3 + \ldots \tag{22}$$

That is, each harmonic contributes an amount to the total power equal to the power it would develop were the other harmonics not present. If, for example, the third harmonic is not present in the current wave, then this harmonic contributes nothing to the average power even though there may be a large third harmonic in the voltage wave. Again, when a 25-cycle alternating emf E_{25} and a direct emf E_d are acting in series on the same circuit the power developed is the sum of the powers which each would develop if they acted separately, but the resultant emf of the combination is not $E_{25} + E_d$, but, as noted above,

$$\sqrt{E_{25}^2 + E_d^2}$$

LINEAR CIRCUITS

10. CIRCUIT EQUATIONS AND VECTOR IMPEDANCES

Practically all steady-state calculations of electric circuit problems are carried out by means of the *complex number* or *vector* method based on the differential equations for the electric charge in terms of the physical parameters of the electric circuit and the impressed voltages. This method is given in detail in Handbook of Engineering Fundamentals, Eshbach, John Wiley & Sons, "Electricity and Magnetism," and is abstracted here. This method is valid only when the resistances, inductances, and capacitances in the network under consideration are constants. Various means are available for extending the method in order to obtain good approximations when these parameters are not constants. Some of these are given in the chapters entitled "Non-Linear Circuits" and "Electrical Machines."

The following are the rules for finding the steady-state currents produced in a network by a group of sinusoidal electromotive forces of a given frequency:

(*a*) Write the differential equations for the instantaneous values of the currents in the network. These will be of the form

$$r_{11} i_1 + L_{11}\frac{di_1}{dt} + \frac{1}{C_{11}}\int i_1\,dt - r_{12} i_2 - L_{12}\frac{di_2}{dt} - \frac{1}{C_{12}}\int i_2\,dt \pm M_{12}\frac{di_2}{dt}$$

$$+ \text{ other terms involving the other currents in the network}$$
$$= \text{impressed voltage in mesh 1.}$$

(*b*) Replace each electromotive force in the network by a complex number having a modulus equal to the rms value of the given electromotive force, and a phase angle equal to the phase angle of the given electromotive force (when expressed in cosine form).

(*c*) Replace $\frac{d}{dt}$ by $j\omega$ and $\int dt$ by $\frac{1}{j\omega}$, where ω is the angular velocity of the given sinusoidal electromotive forces and j is the square root of minus one.

(*d*) Replace each current in the network by an unknown complex number, and solve for these complex numbers.

(*e*) The rms value of the various currents are the moduli of the corresponding complex numbers and the phase angles of the currents (when expressed in cosine form) are the phase angles of these complex numbers.

The coefficients of each of the complex number currents in the equations constructed as indicated above will also be complex numbers; these are called *vector impedances* or often simply *impedances*.

Example. The differential equation for the current in a single isolated mesh having resistance, inductance, and capacitance when a 60-cycle voltage having a modulus value E is impressed is

$$ri + L\frac{di}{dt} + \frac{1}{C}\int i dt = \sqrt{2}\,E \cos 120\pi t \tag{1}$$

The complex number * equation is

$$r\mathbf{I} + j\,120\pi L\mathbf{I} + \frac{1}{j\,120\pi C}\mathbf{I} = \mathbf{E} \tag{1a}$$

hence the vector impedance is

$$\mathbf{Z} = r + j\left(120\pi L - \frac{1}{120\pi C}\right) \tag{2}$$

The current in the circuit is

$$i = \sqrt{2}I \cos (120\pi t - \theta) \tag{3}$$

in which

$$I = \frac{E}{\sqrt{r^2 + \left(120\pi L - \dfrac{1}{120\pi C}\right)^2}} \tag{3a}$$

and

$$\theta = \tan^{-1}\frac{120\pi L - \dfrac{1}{120\pi C}}{r} \tag{3b}$$

11. IMPEDANCE, ADMITTANCE, REACTANCE, SUSCEPTANCE

The *impedance* of a portion of an electric circuit to a completely specified periodic current and potential difference is the ratio of the effective value of the potential difference between the terminals to the effective value of the current, there being no source of emf in the portion under consideration. Impedance defined in this way is a real number which in the case of a sinusoidal current and voltage reduces to the modulus value of the vector impedance defined above.

Admittance is defined as the reciprocal of the impedance. The *vector admittance* is the reciprocal of the complex number representing the vector impedance.

Impedance and admittance, as thus defined, both depend upon the frequency and wave shape of the current. Impedance is expressed in the same units as resistance (e.g., ohms), and admittance in the same units as conductance (e.g., mhos).

The *reactance* of a portion of a circuit for a sinusoidal current, and hence for any one of the frequencies of a periodic current, is the ratio of the quadrature component of the potential difference for a particular frequency to the value of the current for that frequency, there being no source of emf in the portion of the circuit under consideration.

The *susceptance* of a portion of a circuit for a sinusoidal potential difference, and hence for any one of the frequencies of a periodic potential difference, is the ratio of the quadrature component of the current for a particular frequency to the value of the potential difference for that frequency, there being no source of emf in the portion of the circuit under consideration.

From the definitions given above it may be shown that for sine-wave currents and voltages of a given frequency the following relations hold for any portion of a circuit:

$$\left.\begin{array}{ll}
\mathbf{Z} = r + jx & \mathbf{Y} = g - jb \\
Z = \sqrt{r^2 + x^2} & Y = \sqrt{g^2 + b^2} \\
\mathbf{Z} = \dfrac{1}{\mathbf{Y}} & \mathbf{Y} = \dfrac{1}{\mathbf{Z}} \\
r = \dfrac{g}{y^2} & g = \dfrac{r}{Z^2} \\
x = \dfrac{b}{y^2} & b = \dfrac{x}{Z^2}
\end{array}\right\} \tag{4}$$

* Vectors are printed in bold face, the modulus value of a vector $\mathbf{A}$ being printed in light face, A.

where r = effective resistance, x = reactance (taken positive when inductive and negative when capacitive), g = effective conductance, b = susceptance (taken positive when inductive and negative when capacitive), Z = impedance, Y = admittance, $\boldsymbol{Z}$ = vector impedance, and $\boldsymbol{Y}$ = vector admittance, all for the given portion of circuit.

12. IMPEDANCES IN SERIES AND PARALLEL

In general any vector impedance can be written in the form

$$\boldsymbol{Z} = r + jx \tag{5}$$

where r is the sum of the resistances and x is the algebraic sum of the reactances of the several portions of the network which make up this impedance.

The vector impedance may also be expressed in the form

$$\boldsymbol{Z} = Z\angle\theta \tag{6}$$

where

$$Z = \sqrt{r^2 + x^2} \tag{7}$$

is the modulus of the complex number $(r + jx)$ and

$$\theta = \tan^{-1}\left(\frac{x}{r}\right) \tag{8}$$

is the phase angle of this complex number.

In eq. (6) the symbol $\angle$ is read "at an angle" (or "phase") and has the same mathematical significance as e^j. Thus $Z\angle\theta$ is *identical* with $Ze^{j\theta}$.

When two or more vector impedances $\boldsymbol{Z}_1$, $\boldsymbol{Z}_2$, etc., are connected in *series*, so that the *same current I flows through each*, the total impedance drop through the group is

$$\begin{aligned} \boldsymbol{V} &= \boldsymbol{Z}_1\boldsymbol{I} + \boldsymbol{Z}_2\boldsymbol{I} + \dots \\ &= (\boldsymbol{Z}_1 + \boldsymbol{Z}_2 + \boldsymbol{Z}_3 + \dots)\boldsymbol{I} \end{aligned} \tag{9}$$

hence two or more vector impedances in series are equivalent to a single vector impedance equal to the sum of several impedances.

When two or more vector impedances $\boldsymbol{Z}_1$, $\boldsymbol{Z}_2$, etc., are connected in *parallel*, so that the *voltage drop is the same for each* the total current through the group is

$$\begin{aligned} \boldsymbol{I} &= \frac{\boldsymbol{V}}{\boldsymbol{Z}_1} + \frac{\boldsymbol{V}}{\boldsymbol{Z}_2} + \dots \\ &= \left(\frac{1}{\boldsymbol{Z}_1} + \frac{1}{\boldsymbol{Z}_2} + \dots\right)\boldsymbol{V} \end{aligned} \tag{10}$$

It is customary to express this law in terms of the vector admittances, $\boldsymbol{Y}_1$, $\boldsymbol{Y}_2$, ... Two or more vector admittances in parallel are equivalent to a single vector admittance equal to the sum of the several admittances.

13. VECTOR POWER

In Art. 4 average power is defined, and in Art. 6 the average power due to a sinusoidal current and voltage of the same frequency was shown to be

$$P = VI\cos(\theta_v - \theta_i) \tag{11}$$

The vector voltage and vector current in this case are

$$\boldsymbol{V} = Ve^{j\theta_v}$$

$$\boldsymbol{I} = Ie^{j\theta_i}$$

of which the product *is not* the average power. The average power is given by the *real part* of the product of the vector voltage by the *conjugate* of the vector current. The *complex power* is given by

$$\begin{aligned} \boldsymbol{P} &= \boldsymbol{V} \times (\text{conjugate of } \boldsymbol{I}) \\ &= VIe^{j(\theta_v - \theta_i)} \\ &= VI\cos(\theta_v - \theta_i) + jVI\sin(\theta_v - \theta_i) \end{aligned} \tag{12}$$

As stated above, the real part of the complex power is the average power. The imaginary part of the complex power is the reactive power. The average power is the actual average rate of transformation by the receiver of electrical energy into some other form of energy. The reactive power measures the rate of interchange of unused electrical energy between the source and receiver.

This power surges back and forth between source and receiver but is not transformed

into any other type of energy; it does not therefore represent a rate of dissipation of energy in the receiver.

When the current and voltage are written in the form

$$V = V_1 + jV_2$$
$$I = I_1 + jI_2$$

the average power is given by

$$P = V_1 I_1 + V_2 I_2 \tag{13}$$

14. EQUIVALENT IMPEDANCES OF A RECEIVER

The receiver at the end of a transmission line is often a motor or other device which contains a back electromotive force. The vector impedance equations for a network containing such a device therefore involve this back electromotive force as one of the electromotive forces in the network. It is often convenient, however, to express the emf in terms of an equivalent impedance drop.

Let the back emf be denoted by E and let the current through the device be I, then the equivalent impedance of the back emf is simply $E/I = Z_e$. If the true impedance of the remainder of the circuit is Z then the impedance equation becomes

$$(Z_e + Z)I = V \tag{14}$$

where V is the voltage impressed across the device.

If the emf leads the current by an angle θ then an amount of electric power

$$P = EI \cos \theta \tag{15}$$

is converted into some other form of power. A resistance which will absorb this same amount of power when the current I flows through it is

$$r_e = \frac{P}{I^2} = \frac{E}{I} \cos \theta \tag{16}$$

This resistance is called the equivalent resistance of the back emf; it is the real part of the vector impedance Z_e. The equivalent reactance of the back emf is

$$x_e = r_e \tan \theta \tag{17}$$

It should be noted that the equivalent impedance of a back emf as given above is a function of the current through the receiver. The quantity $(Z_e + Z)$ is the total equivalent impedance of the receiver.

15. COMPLICATED CIRCUITS

When an electrical network is extremely complicated the process of combining series and parallel impedances in order to solve for the currents in the various branches is quite difficult. In such cases it is usually easier to set up the problem in terms of *mesh currents* instead of branch currents. If currents are assumed to flow around each of the meshes of a network so that the current in any branch is the difference of the mesh currents in the two meshes on either side of that branch, then the impedance equations resulting from the application of Kirchhoff's second law will contain the Kirchhoff point equations. See Handbook of Engineering Fundamentals, Eshbach, John Wiley & Sons, "Direct Current Circuits" and "Alternating Current Circuits."

The mesh equations for a network having n meshes, each mesh containing impressed voltages, are

$$\left.\begin{array}{l} Z_{11} I_1 + Z_{12} I_2 + \dots + Z_{1n} I_n = V_1 \\ Z_{21} I_1 + Z_{22} I_2 + \dots + Z_{2n} I_n = V_2 \\ \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \\ Z_{n1} I_1 + Z_{n2} I_2 + \dots + Z_{nn} I_n = V_n \end{array}\right\} \tag{18}$$

in which Z_{jj} is the self-impedance of the jth mesh and Z_{jk} is the mutual impedance of the jth mesh with respect to the kth mesh. Z_{jk} is always equal to Z_{kj} in passive networks and in active networks in which there is no valve action.

A representative network of this type is shown in Fig. 1; in this network the number of meshes is easy to count. In general, as for example when the network cannot be drawn on the surface of a sphere, the number of mesh currents necessary to formulate the problem completely is

$$B - V + S$$

where B = the number of branches, V = the number of intersections or vertices, and S = the number of separate parts. A circuit which closes on itself (single mesh) is assumed to have one intersection.

These impedance equations can be solved by the substitution method or by the method of determinants. For numerical calculations it is usually simpler to solve by substitution and elimination of currents. In theoretical work, however, particularly in the development of the general properties of electrical networks, the method of determinants is much more powerful.

The values of the currents in eq. (18) can be calculated by means of Cramer's rule which is developed in the theory of linear algebraic equations and determinants.

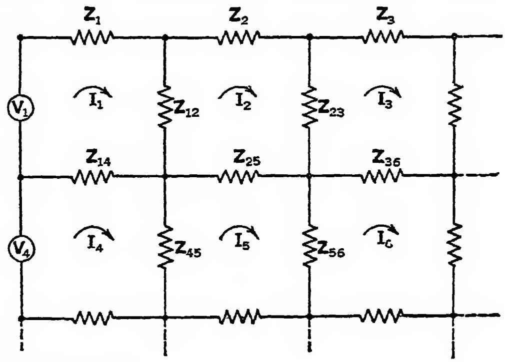
Let D denote the determinant of order n whose elements are the Z's in eqs. (18), i.e.,

$$D = \begin{vmatrix} Z_{11} & Z_{12} & \dots & Z_{1n} \\ Z_{21} & Z_{22} & \dots & Z_{2n} \\ \cdot & \cdot & \cdot & \cdot \\ Z_{n1} & Z_{n2} & \dots & Z_{nn} \end{vmatrix} \tag{19}$$

and let M_{jk} denote the determinant of order $n - 1$ obtained from D by deleting the jth row and the kth column of that determinant. M_{jk} is called a minor of D. Further let

$$A_{jk} = (-1)^{j+k} M_{jk} \tag{20}$$

A_{jk} is called a cofactor of D.



$Z_{11}=Z_1+Z_{12}+Z_{14}$

$Z_{22}=Z_2+Z_{12}+Z_{23}+Z_{25}$

Etc.

FIG. 1. Complicated Network. The network shown is *not* perfectly general but is given here for illustration; the network corresponding to eqs. (18) cannot be drawn on a plane

Then the current I_k is given by

$$I_k = \sum_{k=1}^{n} \frac{A_{jk} V_j}{D} \tag{21}$$

16. RECIPROCAL THEOREM

Let a single impressed voltage V be applied to, say, the jth mesh of a network, all other impressed voltages being zero. The current in the kth mesh is

$$I_k = \frac{A_{jk} V}{D}$$

Now let the voltage be removed from the jth mesh and inserted in the kth mesh. The current in the jth mesh in this case is

$$I_j = \frac{A_{kj} V}{D}$$

Since $Z_{jk} = Z_{kj}$ it follows also that $A_{jk} = A_{kj}$, hence the theorem commonly called the *reciprocal theorem*:

The current in a given branch of a network due to an electromotive force in another branch of the network is the same as the current which would be produced in the second branch of the network if the electromotive force were transferred to the first branch.

The quantity A_{kj}/D is called the *transfer admittance* from the kth to the jth mesh. The reciprocal of this quantity is the *transfer impedance*.

17. THÉVENIN'S THEOREM

A theorem due to Thévenin, which can be deduced from eqs. (18), is extremely valuable in network problems inasmuch as it allows the calculation of the performance of a device from its terminal properties only, without inquiring into its internal make-up.

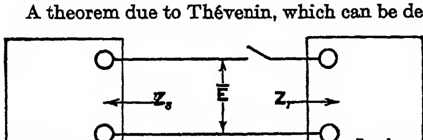


FIG. 2. Junction of a Source and Receiver

Consider any complicated network having internal electromotive forces and having two available points of entry, such as that shown in Fig. 2. Such a network is capable of acting as a source of electrical

energy. Let E be the open-circuit terminal voltage of this source, and let the impedance *looking into* the source terminals be Z_s. (By impedance "looking into" a pair of terminals is meant the input impedance measured at these terminals with the rest of the network disconnected, and all emf's made equal to zero.) Let this source be connected to a receiver having two points of entry and containing no internal emf's. The impedance looking into the receiver terminals will be taken as Z_r. Then Thévenin's theorem states that the current which flows from source to receiver is given by

$$(Z_r + Z_s)I = E \tag{22}$$

A generalization of this statement may be stated thus:

If two networks are connected together by means of a two-conductor line the line current is equal to the algebraic sum of the open-circuit voltages which would appear if the line were cut, divided by the sum of the impedances looking toward the source and toward the receiver from the cut.

A simple use of this theorem is the calculation of the current delivered to a motor by a generator. In this case the generator emf minus the motor back emf divided by the sum of the two internal impedances plus the line impedance yields the line current.

18. EQUIVALENT TRANSDUCERS (T AND π)

It is often desirable to study the performance of a network at two pairs of its terminals when various voltages or various impedances are connected to them. In such cases it is convenient to call one pair of terminals the input terminals and the other pair the output terminals. The input terminals are those usually connected to a source of energy, and the output terminals are those usually connected to a receiver. Both terminals may, of course, be connected to sources. A device of this type having one pair of input terminals and one pair of output terminals is called a *transducer*. A transformer, an underground cable, a transmission line together with its terminal transformers, etc., are transducers.

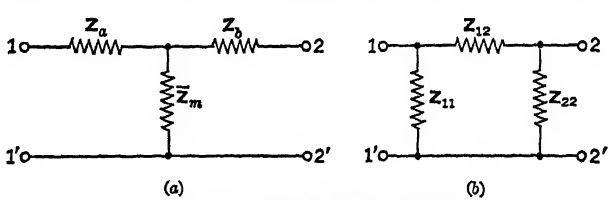

FIG. 3. Equivalent T and π Sections

Any *passive* transducer, i.e., one which does not contain a source of electromotive force, may, for a given frequency, be replaced by an equivalent circuit containing only three independent impedances. These impedances may be arranged as in Fig. 3*a* or as in Fig. 3*b*. The former arrangement is called an equivalent T; the latter arrangement is called an equivalent π of the given transducer.

The constants of the equivalent T may be computed from measurements made at the terminals of the given network. Let:

Z_{10} = impedance measured at the input terminals when the output terminals are open.
Z_{20} = impedance measured at the output terminals when the input terminals are open.
Z_{1s} = impedance measured at the input terminals when the output terminals are short-circuited.
Z_{2s} = impedance measured at the output terminals when the input terminals are short-circuited.

These quantities are not all independent, the relation

$$Z_{10}\, Z_{2s} = Z_{20}\, Z_{1s} \tag{23}$$

providing a means for calculating any one when the other three are known.

In terms of these open- and short-circuit impedances the parameters of the equivalent T are:

$$Z_m = \sqrt{Z_{20}(Z_{10} - Z_{1s})} \tag{24}$$

$$Z_a = Z_{10} - Z_m \tag{25}$$

$$Z_b = Z_{20} - Z_m \tag{26}$$

Other forms for these equations may be obtained by the use of eq. (23). It is sometimes convenient to make use of the transfer impedance of the transducer in these calcula-

tions. The transfer impedance Z_{ts} can of course be measured directly; it is related to the open- and short-circuit impedances by:

$$Z_{ts} = Z_{1s}\sqrt{\frac{Z_{20}}{Z_{10} - Z_{1s}}} \tag{27}$$

The shunt arm Z_m of the equivalent T may also be expressed as:

$$Z_m = \frac{Z_{10}\,Z_{2s}}{Z_{ts}} \tag{28}$$

The impedances in the equivalent π may be calculated from those of the equivalent T by the formulas:

$$Z_{11} = Z_a\,Z_m\left(\frac{1}{Z_a} + \frac{1}{Z_b} + \frac{1}{Z_m}\right) \tag{29}$$

$$Z_{22} = Z_b\,Z_m\left(\frac{1}{Z_a} + \frac{1}{Z_b} + \frac{1}{Z_m}\right) \tag{30}$$

$$Z_{12} = Z_a\,Z_b\left(\frac{1}{Z_a} + \frac{1}{Z_b} + \frac{1}{Z_m}\right) \tag{31}$$

19. GENERAL CIRCUIT CONSTANTS

Another method of specifying a transducer is by means of the four constants A, B, C, and D defined by the equations:

$$E_s = AE_r + BI_r \tag{32}$$

$$I_s = CE_r + DI_r \tag{33}$$

in which the subscript s stands for source and the subscript r stands for receiver.* These constants are no more "general" than those described in the preceding article; they have the advantage, however, of expressing the source conditions, directly in terms of the receiver conditions. The constants A, B, C, and D are not independent. Any one can be calculated, when the other three are known, by the equation:

$$AD - BC = 1 \tag{34}$$

This relation may be used to deduce from eqs. (32) and (33) the alternative forms:

$$E_r = DE_s - BI_s \tag{35}$$

$$I_r = -CE_s + AI_s \tag{36}$$

These equations have the advantage of expressing the receiver conditions directly in terms of the conditions which obtain at the source.

General circuit constants are of great value in the calculation of the performance of power systems and in studies of stability (q.v.).

The general circuit constants may be calculated from the constants of the equivalent T by the formulas:

$$\left.\begin{aligned} A &= 1 + \frac{Z_a}{Z_m} \\ B &= Z_a + Z_b + \frac{Z_a\,Z_b}{Z_m} \\ C &= \frac{1}{Z_m} \\ D &= 1 + \frac{Z_b}{Z_m} \end{aligned}\right\} \tag{37}$$

The general circuit constants may also be calculated from the constants of the equivalent π, thus

$$\left.\begin{aligned} A &= 1 + \frac{Z_{12}}{Z_{22}} \\ B &= Z_{12} \\ C &= \frac{1}{Z_{11}} + \frac{1}{Z_{22}} + \frac{Z_{12}}{Z_{11}\,Z_{22}} \\ D &= 1 + \frac{Z_{12}}{Z_{11}} \end{aligned}\right\} \tag{38}$$

* E_s and E_r are voltage *rises* in source and receiver, respectively; I_s is the current flowing *into* the network from the source and I_r is the current flowing *out* of the network to the receiver.

It is interesting to note that A and D are pure numerics; from eqs. (32) and (33) it is apparent that A is the open-circuit voltage ratio and that D is the short-circuit current ratio of the transducer.

The constant B has the dimensions of impedance whereas the constant C has the dimensions of admittance. From eq. (32) the constant B may be recognized as the transfer impedance of the transducer. The constant C, from eq. (33), may be seen to be the ratio of source current to receiver voltage when the receiver terminals are open. These physical meanings which attach themselves to the general circuit constants provide means for their direct measurement.

If two transducers are connected in series, the general circuit constants of the resulting transducer are easily expressible in terms of the general circuit constants of the separate transducers. Let A_1, B_1, C_1, and D_1 be the general circuit constants of the first and A_2, B_2, C_2, and D_2 the general circuit constants of the second transducer, then if A_s, B_s, C_s, D_s be the general circuit constants of the transducer formed by the two in series, we have:

$$\left.\begin{aligned} A_s &= A_1 A_2 + B_1 C_2 \\ B_s &= A_1 B_2 + B_1 D_2 \\ C_s &= C_1 A_2 + D_1 C_2 \\ D_s &= C_1 B_2 + D_1 D_2 \end{aligned}\right\} \qquad (39)$$

If A_p, B_p, C_p, D_p be the general circuit constants of the transducer formed by the two transducers in parallel we have:

$$\left.\begin{aligned} A_p &= \frac{A_1 B_2 + B_1 A_2}{B_1 + B_2} \\ B_p &= \frac{B_1 B_2}{B_1 + B_2} \\ C_p &= C_1 + C_2 + \frac{(A_1 - A_2)(D_2 - D_1)}{B_1 + B_2} \\ D_p &= \frac{B_1 D_2 + D_1 B_2}{B_1 + B_2} \end{aligned}\right\} \qquad (40)$$

Since A, B, C, and D for a given transducer are not independent, slightly more work is done in calculation of these constants than if three independent constants were used; this, however, affords an extremely valuable check of the numerical computation. Eq. (34) may be checked at various stages throughout a lengthy calculation, it being extremely unlikely that this equation will be satisfied if a numerical error has been made.

20. GENERAL N-TERMINAL NETWORK

It is possible, given an electrical network with any number of points of entry, to obtain a circuit having the same number of points of entry which cannot be distinguished from the given circuit by any single-frequency electrical tests made at the terminals. This equivalence is independent of any arbitrary pairing of terminals and hence is more general than the transducer equivalence discussed in Arts. 18 and 19.

The performance of a network having $(n + 1)$ points of entry is determined by $n(n + 1)/2$ independent impedance links. This becomes apparent if the mesh equations are written down. Referring to the network of Fig. 4, assume that equations have been written down for all the currents in the network and that the resulting system of equations has been reduced by elimination of currents until there remain n equations in n of the $(n + 1)$ branch currents indicated. The remaining branch current is then determined since the sum of all $(n + 1)$ currents must be zero. The impedance equations are of the form given by eq. (18). Since $Z_{jk} = Z_{kj}$ the number of independent impedances in eq. (18) is $n(n + 1)/2$.

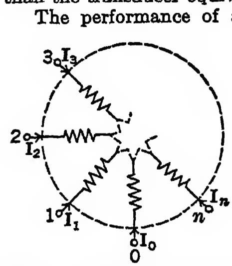

FIG. 4. General Network Having n Points of Entry

If a new network is set up, having the same number of points of entry as the given network, in which each point of entry is connected with every other point of entry through an impedance, the total number of impedances in the new network is the number of combinations of $(n + 1)$ things taken 2 at a time, which is $n(n + 1)/2$.

It is possible to solve for the $n(n + 1)/2$ new impedances in terms of the $n(n + 1)/2$ impedances of the given network so as to preserve equality of branch currents in any set

of single-frequency impressed voltages. The method of doing this is illustrated in Art. 21 by means of a four-terminal network. This may readily be generalized to any number of terminals.

An equivalent network of this type is sufficiently general for any steady-state calculations and is valuable in the representation of complex networks on calculating boards.

21. GENERAL FOUR-TERMINAL NETWORK

Let the general four-terminal network be represented by Fig. 5*a*, and let the network which we propose to make equivalent to it be represented by Fig. 5*b*. Terminal 0 will be considered as a reference or "ground" terminal in both cases. In other words the impressed voltages will be thought of as being V_{10}, V_{20}, and V_{30}, all other voltages being differences of these. All quantities in (*a*) will be differentiated from corresponding quantities in (*b*) by a prime. It is required that the currents I'_1, I'_2, and I'_3 be equal to I_1, I_2, and I_3, respectively, when V'_{10}, V'_{20}, and V'_{30} are equal to V_{10}, V_{20}, and V_{30}, respectively.

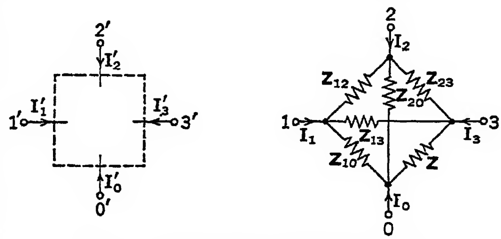

FIG. 5. General Four-terminal Networks

The equations for the currents in the given network are of the form

$$\left.\begin{aligned} A_{11} I'_1 + A_{12} I'_2 + A_{13} I'_3 &= V'_{10} \\ A_{12} I'_1 + A_{22} I'_2 + A_{23} I'_3 &= V'_{20} \\ A_{13} I'_1 + A_{23} I'_2 + A_{33} I'_3 &= V'_{30} \end{aligned}\right\} \tag{41}$$

The solution of these equations may be found by a simple transformation to be

$$\left.\begin{aligned} I'_1 &= B_{11} V'_{10} + B_{12} V'_{20} + B_{13} V'_{30} \\ I'_2 &= B_{12} V'_{10} + B_{22} V'_{20} + B_{23} V'_{30} \\ I'_3 &= B_{13} V'_{10} + B_{23} V'_{20} + B_{33} V'_{30} \end{aligned}\right\} \tag{42}$$

in which the B's are equivalent admittances calculable from the actual network impedances by ordinary algebra of complex numbers.

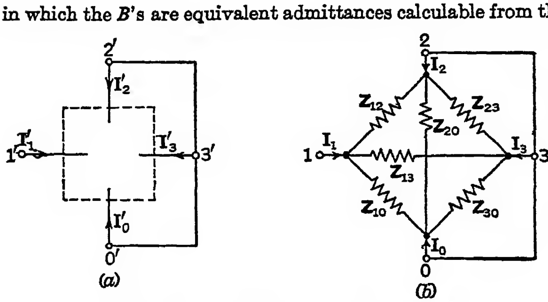

FIG. 6. General Four-terminal Networks

Short all terminals except the first to the reference terminal as shown in Fig. 6 (*b*). It follows that in the (*a*) network the currents are given by

$$\left.\begin{aligned} I'_1 &= B_{11} V'_{10} \\ I'_2 &= B_{12} V'_{20} \\ I'_3 &= B_{13} V'_{30} \end{aligned}\right\} \tag{43}$$

In the (*b*) network a current entering the common bus from any terminal is simply the current in that branch of the network which joins the given terminal with terminal 1. This is due to the fact that no current flows in any of the branches which are short-circuited by the common bus. The currents are

$$\left.\begin{aligned} I_2 &= -\frac{V_{10}}{Z_{12}} \\ I_3 &= -\frac{V_{10}}{Z_{13}} \\ I_0 &= -\frac{V_{10}}{Z_{10}} \end{aligned}\right\} \tag{44}$$

Comparing eqs. (43) and (44) the two simple relations

$$\left.\begin{aligned} Z_{12} &= -\frac{1}{B_{12}} \\ \text{and} \qquad Z_{13} &= -\frac{1}{B_{13}} \end{aligned}\right\} \tag{45}$$

are observed. By shorting the terminals in other groupings the following general equations may be verified:

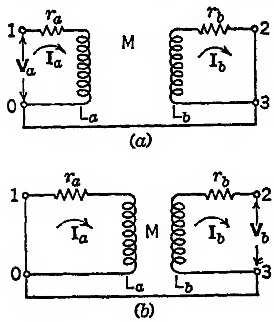

FIG. 7. Air-core Transformer

$$Z_{jk} = -\frac{1}{B_{jk}} \tag{46}$$

It may be shown that the equivalent circuit of a network having *any* number of points of entry follows the same scheme and that eq. (46) also holds.*

Example.—The general equivalent circuit of a two-winding transformer is easily found by the method outlined. Let the primary terminals be 0 and 1 and let the secondary terminals be 2 and 3. The mesh equations when all terminals except terminal 1 are strapped together are (refer to Fig. 7*a*)

$$\begin{aligned} (r_a + j\omega L_a)I_a - j\omega M I_b &= V_a \\ -j\omega M I_a + (r_b + j\omega L_b)I_b &= 0 \end{aligned} \tag{47}$$

in which I_a and I_b are the primary and secondary mesh currents. The following relations are apparent, comparing the transformer with Fig. 6:

$$\left.\begin{aligned} I_a &= I'_1 = -I'_0 \\ I_b &= I'_3 = I'_2 \\ V_a &= V'_{10} \end{aligned}\right\} \tag{48}$$

Hence we have

$$B_{12} = -\frac{j\omega M}{D} \tag{49}$$

$$B_{13} = \frac{j\omega M}{D} \tag{50}$$

in which

$$D = (r_a + j\omega L_a)(r_b + j\omega L_b) + \omega^2 M^2 \tag{51}$$

Similarly, when all terminals except terminal 2 are strapped together the mesh equations are (see Fig. 7*b*):

$$\begin{aligned} (r_a + j\omega L_a)I_a - j\omega M I_b &= 0 \\ -j\omega M I_a + (r_b + j\omega L_b)I_b &= V_b \end{aligned} \tag{52}$$

In this case the relations between I_a and I_b and the currents of Fig. 6 remain unchanged but V_b now corresponds to V_{02}. Hence we have

$$B_{12} = -\frac{j\omega M}{D} \tag{53}$$

$$B_{23} = -\frac{r_a + j\omega L_a}{D} \tag{54}$$

From the relation $B_{jk} = -\frac{1}{Z_{jk}}$ and from symmetry the Z's of the equivalent network are

$$Z_{10} = \frac{(r_a + j\omega L_a)(r_b + j\omega L_b) + \omega^2 M^2}{r_b + j\omega L_b}$$

$$Z_{23} = \frac{(r_a + j\omega L_a)(r_b + j\omega L_b) + \omega^2 M^2}{r_a + j\omega L_a}$$

$$Z_{12} = Z_{30} = \frac{(r_a + j\omega L_a)(r_b + j\omega L_b) + \omega^2 M^2}{j\omega M}$$

$$Z_{13} = Z_{20} = \frac{(r_a + j\omega L_a)(r_b + j\omega L_b) + \omega^2 M^2}{-j\omega M}$$

The circuit is shown in Fig. 8. This circuit cannot be realized in practice owing to the fact that negative resistances would be required. In order to eliminate this difficulty

* Starr, F. M., Equivalent circuits—I. *Trans. A.I.E.E*, Feb., 1932.

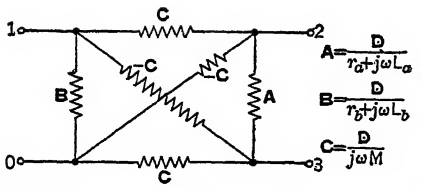

FIG. 8. Equivalent Circuit of a Two-winding Transformer

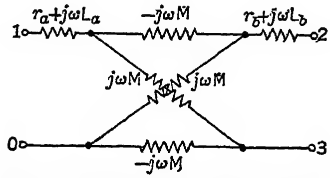

FIG. 9. Equivalent Circuit of a Two-winding Transformer (having positive resistance only)

and to obtain a circuit which could be used on a calculating board it is desirable to transform this network, if possible, into one having positive resistances only. This has been done by Starr (*loc cit.*); the equivalent circuit is shown in Fig. 9.

NON-LINEAR CIRCUITS

A non-linear circuit is one in which one or more of the circuit elements, resistance, inductance, or capacitance, depends upon one or more of the currents flowing in the circuit. Variable electric circuits in which the resistances, inductances, or capacitances are functions of time or position in space, but not dependent upon the currents, are not non-linear but require special methods for their solutions. Some of these are given in the chapter on Electrical Machines.

The outstanding feature of a non-linear circuit is the production of component frequencies of current other than those corresponding to impressed voltages or natural periods.

In the present chapter the most important types of non-linearity arising in electric power circuits are described; the various methods for solving networks involving them are outlined.

22. FERROMAGNETISM

A ferromagnetic material is one having a permeability greater than that of a vacuum. The permeability of such materials is ordinarily a function of the magnetizing force and dependent upon the previous history of the sample under consideration.

When any completely demagnetized ferromagnetic substance is subjected to an increasing magnetizing force H, a curve such as the dotted curve in Fig. 1*a* results. Such a curve is variously termed a *rising characteristic*, a *virgin curve*, or a *neutral curve*; all these names are reserved for the special case of a magnetization curve of a *demagnetized* body.

If, from any positive value of H, the magnetizing force is decreased, the flux density

will also decrease, but not along the same curve as the original rising characteristic. For the decreasing values of H, B is greater than for the corresponding values on the rising characteristic. The magnetized body retains a part of its magnetization. It will be noticed that, when the magnetizing force is reduced to zero, there is still a positive value of B, which is dependent upon the maximum positive value of H on the rising characteristic, before H is decreased. The flux density which remains when H has been reduced to zero is called the *residual magnetism* and is in the nature of permanent or semi-permanent magnetism. If now the magnetizing force is reversed (e.g., by reversing the direction of the current through the magnetizing coil), a value of H will be found which will reduce B to zero. This value of H is called the *coercive force.* By proceeding through a cycle of values for the magnetizing force—from zero to a positive maximum, to zero, to a negative maximum, and back to zero—a loop of flux densities will be obtained. Such a loop is called a *hysteresis loop*; each substance is capable of having an infinity of different hysteresis loops depending on the conditions of magnetization. During part of the magnetizing cycle the electric circuit is transferring energy to the magnetic circuit,

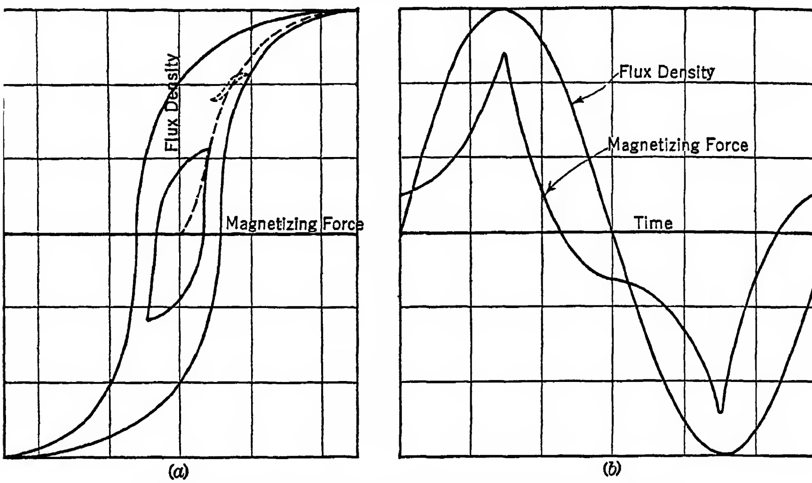

FIG. 1. Magnetization Curves and Wave Form of Magnetizing Force

and during the remainder of the cycle energy is retransferred from the magnetic to the electric circuit. When any ferromagnetic substance is present in the magnetic circuit more energy is transferred to the magnetic circuit than is retransferred to the electric circuit. The difference between these two amounts of energy is a loss and is dissipated by heat. Part of this loss is called the *hysteresis loss* and is presumably due to molecular friction accompanying the change in orientation of the elementary molecular magnets within the ferromagnetic substance. It may be shown that the hysteresis loss per cycle per cubic centimeter in any magnetic substance due to a complete cycle of changes of the flux density and the magnetizing force is equal to $\frac{1}{4\pi}$ times the area of the corresponding hysteresis loop, provided this loop is determined under such conditions that there is no mechanical motion and no change in the relative distribution of the lines of force. This relation is based on the further assumption that unit distance on one scale represents one gauss and that unit distance on the other scale represents one oersted. The following empirical formula is useful in determining hysteresis loss.

$$w = \eta B_m^{1.6} \text{ ergs per cubic centimeter per cycle} \qquad (1)$$

where η is a coefficient depending upon the substance and B_m is the maximum flux density reached during the cycle.

The power loss per unit weight of magnetic material is given by

$$P_h = kfB_m^{1.6} \text{ watts per pound} \qquad (2)$$

where f is the frequency in cycles per second and k is constant.

If the value of B varies sinusoidally with time, as is approximately true in many practical cases, the value of H at any instant of time can be found graphically from the

hysteresis loop as shown in Fig. 1(*b*). This is of value in calculating exciting currents of transformers and machines.

If, as sometimes happens, the variation of magnetizing force with time is such that there is more than one maximum and one minimum value per cycle, the above formulas for power loss and the above graphical construction are not valid. In such cases the hysteresis loop has interior loops as indicated by the dotted loop in Fig. 1(*a*). The shape of such interior loops and the power loss corresponding to them will depend upon the value of H at which the loop occurs and the width of the loop. No simple method has been devised to calculate circuits in which this occurs even when all the data are known since ordinarily the character of the B versus H curve cannot be found except by direct measurement under the specified conditions.

For detailed information, including tables and curves, refer to Sect. 2, Magnetic Materials.

23. EDDY CURRENTS

Since a varying magnetic field induces an emf in any closed circuit which it links, it will in general cause a flow of current in the magnetic materials composing the magnetic circuit. Such currents are called *eddy currents* or *Foucault currents* and cause rI^2 losses. Eddy currents can be distinguished from ordinary induced currents by the fact that they are due solely to the lines of force which pass *through* the space occupied by the conducting mass. Ordinary induced currents are produced by lines of force which *link* the conductor but do not pass through the space occupied by the conducting mass. It is customary wherever possible to laminate magnetic cores in order to increase the resistance of the path of induced eddy currents. The eddy-current loss in metal sheets is given by

$$P_e = \frac{\pi^2}{6 \times 10^{16}} \rho (afB_m)^2 \text{ watts per cubic centimeter} \tag{3}$$

where ρ is the resistivity of the material, a is the thickness of each sheet, f is the frequency of the eddy currents, and B_m is the maximum value of the flux density during a cycle. Eq. (3) holds provided (*a*) that the lines of force are parallel to the planes of the laminations, (*b*) that the laminations are thoroughly insulated from each other, and (*c*) that the thickness of each lamination is small in comparison with its other dimensions. The combination of hysteresis loss and eddy current is called the *total core loss*. A method of calculating circuits in which eddy currents are of importance is given in Art. 29.

24. SKIN EFFECT

A conductor of finite cross-section may be looked upon as made up of separate filaments each carrying its portion of the total current. When the same potential gradient is established through all the filaments of the conductor the exterior filaments are linked by fewer flux lines than the interior filaments. If the emf producing the potential gradient through the wire is an alternating one, the induced back emf in the interior filaments will be greater than in those nearer the surface. Since the potential drop is the same across all the filaments the resistance drops in the internal filaments are less than in the external filaments. This can be brought about only by the current distributing itself over the cross-section of the conductor in such a manner that the current density in the interior of the wire will be less than at the surface, i.e., the current is forced toward the surface filaments or " skin " of the wire; hence the term skin effect is applied to this phenomenon.

The self-induced emf depends not only upon the amount of flux set up but also upon the rapidity of its variations; hence the skin effect becomes more pronounced the greater the frequency of the impressed emf. It is also greater the larger the cross-section of the conductor, the greater the conductivity of the conductor, and the greater its magnetic permeability. It also depends slightly upon the temperature since the conductivity changes with temperature.

As a consequence of the skin effect the effective resistance of a conductor to alternating currents is greater than to direct currents, but the *internal* inductance *decreases* with the frequency; the external inductance is not altered. Whereas, however, the internal inductance with increasing frequency approaches a limiting value, the resistance increases indefinitely as the frequency approaches an infinite value. The change of resistance is always relatively much larger than the change in the total inductance.

The effects just described are, for the most part, negligible at low frequencies, except in heavy conductors and in coils wound with stout wire in several layers. In the latter case, however, the diminution of the inductance, due to the irregular distribution of the current, is masked, to a greater or less degree, by the effect of the capacitance between the

windings of the coil, which gives rise to an *increase* of the inductance with the frequency. For the same reason the resistance is increased more than it would be by the eddy currents alone.

Unfortunately, the rigorous or approximate solution of the problem at high frequencies for the various cases which arise in practice is in many instances very difficult, if not impossible.

The above has considered the redistribution of the current stream lines due to the current in the conductor itself. If there are other current carrying conductors in the vicinity a further redistribution of the current stream lines will occur, producing an additional change in resistance and inductance. This is called the *proximity effect.*

For a mathematical analysis of skin effect refer to A. Russel, *Phil. Mag.* 17, p. 524, 1909; J. R. Carson, *Phil. Mag.* 41, p. 607, April, 1921; Sallie Pero Mead, *B.S.T.J* 4, No. 2, April, 1925.

Electrot.* 26, pp. 513–517, July 5, 1932; Forbes, H. C., and Gorman, L. J., Skin Effect in Rectangular Conductors, *Trans. A.I.E.E.* 52, pp. 516–519; Disc., pp. 519–520, June, 1933, *Elect. Eng.* 52, pp. 636–639, Sept., 1933.

SKIN EFFECT IN STRAIGHT ROUND WIRES. An accurate solution for the case of straight *solid* * wires of circular cross-section has been given in a number of different forms by various scientists. A summary of the formulas is given in a paper by Rosa and Grover, Bull. Bur. Standards, Vol. 8, p. 172, 1912. The calculations are most conveniently made by the use of the tables given in Rosa and Grover's paper, which are given in a condensed form in Table 1. Let

f = frequency in cycles per second,
μ = permeability of the wire, *assumed constant,*
R = direct-current resistance, in ohms, of 1000 ft of the wire; see tables in the article on Wires and Cables, Bare, Sect. 14, §47.
L = direct-current inductance, in millihenrys per 1000 ft. of a *non-magnetic* wire of the same *cross-section* as that of the given wire, and at the given spacing between wires, see tables in the article on Inductance and Inductive Reactance, Sect. 14, §22.

Calculate the quantity
$$x = 0.02768\sqrt{\frac{\mu f}{R}} \tag{4}$$

and take from Table 1 the corresponding values of K_1 and K_2. Then the alternating-current resistance at the frequency f is

$$R' = K_1 R \qquad \text{ohms per 1000 ft} \tag{5}$$

and the alternating-current inductance of the given wire at the frequency f is

$$L' = L + 0.01524\,(\mu K_2 - 1) \qquad \text{millihenrys per 1000 ft} \tag{6}$$

For x greater than 7 the following relations hold to within less than 1 per cent, the error being less the greater the value of x:

$$R' = \left(\frac{x}{2.828} + 0.25\right)R \tag{7}$$

$$L' = L + 0.01524\left(\frac{2.828\,\mu}{x} - 1\right) \tag{8}$$

SKIN EFFECT IN THIN STRIPS AND TUBES. The following formulas are exact for a flat strip of infinite width and at an infinite distance from any other conductor carrying a current; they also apply with a close degree of approximation to a tube which has a circumference 10 or more times its thickness, provided no other conductor carrying a current is closer than a distance of 10 times the thickness of the strip or tube.

Let t = thickness of strip, or *twice* the thickness of the wall of a tube, in centimeters,
w = width of strip or *half* the mean circumference of tube, in centimeters,
l = length of strip or tube in centimeters,

* Tests at the Massachusetts Institute of Technology (*Proc. A.I.E.E.*, Sept., 1915), indicate that the formulas for solid wires also apply to round *stranded* wires of the *same cross-section of metal,* not the same over-all diameter, for frequencies up to 1200, but above this frequency there is an increase in the skin effect, due to the spiraling of the component wires of the cable.

ρ = specific resistance of conductor, in microhms per centimeter cube, at the given temperature,
μ = magnetic permeability of conductor in absolute units,
f = frequency in cycles per second,
$x = 0.1987\, t\sqrt{\frac{\mu f}{\rho}}$.

Then d-c resistance is $$R = \frac{10^{-6}\,\rho l}{wt} \text{ ohms}$$

The d-c internal inductance is

$$L_i = 1.047 \times 10^{-6}\, l\frac{\mu t}{w} \text{ millihenrys}$$

The ratio of the a-c to the d-c resistance is

$$\frac{R'}{R} = \frac{x}{2}\left(\frac{\sinh x + \sin x}{\cosh x - \cos x}\right)$$

and the ratio of the a-c to the d-c internal inductance is

$$\frac{L'_i}{L_i} = \frac{3}{x}\left(\frac{\sinh x - \sin x}{\cosh x - \cos x}\right)$$

For x less than unity these ratios are unity to within 0.6 and 0.2 per cent, respectively, i.e., the a-c resistance is practically equal to the d-c resistance and the a-c internal inductance is practically equal to the d-c internal inductance. For x greater than 6 the following formulas are accurate to within 0.5 per cent:

$$\frac{R'}{R} = \frac{x}{2} \quad \text{and} \quad \frac{L'_i}{L_i} = \frac{3}{x}$$

To a very rough degree of approximation the skin effect in a conductor of any shaped cross-section may be approximated by using the above formulas for a strip, taking for the effective width w one-half the perimeter of the section (in centimeters) and for its effective thickness twice the area of the section (in square centimeters) divided by its perimeter. In general, then, for the same area the skin effect will be less the greater the perimeter of the section. If the section approaches more nearly that of a solid circle than that of an elongated rectangle, the formulas for a solid round wire will give more accurate results.

SKIN EFFECT IN BUS-BARS (STRIPS OF FINITE WIDTH). The formulas given above are for strips of infinite width; the skin effect in narrow strips, such as used for bus-bars, is much greater than the theoretical value for infinite strips, owing to the crowding of the current to the edge of the strip. This latter effect has been called the "edge effect." Experimental results obtained by Kennelly, Laws and Pierce (*Proc. A.I.E.E.*, September, 1915), for strip conductors, outgoing and return conductor 60 cm apart, are given in Fig. 2. For other spacings the original paper should be consulted.

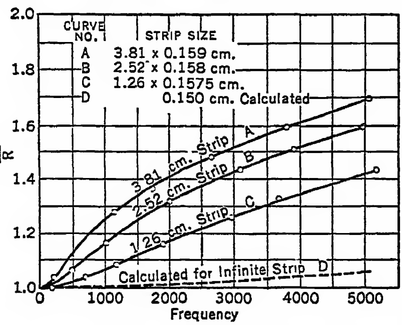

FIG. 2. Skin Effect in Finite Strips. Return conductor 60 cm away

In the *Journal of the Franklin Institute* for March, 1918, are reported tests on copper bus-bars 4 in. by 1/4 in., showing a ratio of a-c to d-c resistance of 1.3 at 60 cycles and 1.1 at 24 cycles. It is stated that this increase in resistance is due chiefly to the crowding of the current toward the edge of the strip, and not to the sides. Three such bars in parallel with an air space of 0.25 in. between them gave a ratio of a-c to d-c resistance of 2.2 at 60 cycles.

SKIN EFFECT IN TRANSMISSION LINES. For a comprehensive treatment of effective resistance and inductance of bimetallic (copper-clad steel) and also of iron wires, see Miller, J. M., Bull. Bur. Standards, 12, p. 207, 1915. For tables of skin-effect ratios for concentric-lay and annular conductors see Sect. 14, Art. 50.

25. ELECTRIC ARCS

An electric arc is an incandescent vapor bridge consisting of material electrically impelled from a negative to a positive electrode. A spark is also an incandescent vapor bridge, but differs from an arc in not depending upon the electrodes for its material medium. The establishment and maintenance of an arc require the expenditure of energy for the latent heat of evaporation of the electrode and for the motion of the vapor stream. As no energy can be expended for these purposes until a current flows, an arc cannot start spontaneously. The following expedients are, therefore, adopted to start arcs:

1. Bringing the electrodes into contact with each other and separating them after the current has commenced to flow.
2. Stressing the dielectric between the conductors by overvoltage until it breaks down electrically and becomes conducting.
3. Using a subsidiary arc to furnish the initial vapor bridge.

The first of these methods is used in carbon-arc lamps and the last in mercury-arc rectifiers.

A peculiarity of the carbon arc is that, with any particular length of arc, if the current be increased the difference of potential across the carbons will decrease. This occurs continuously up to a certain point when in the open arc the voltage drops quite suddenly. If the current is still increased the voltage will again become steady at a much lower value. Between the values before and after the drop the arc is unstable and emits a hissing sound. In inclosed arcs the hissing point is absent and the curve is continuous.

The relation between the drop of potential across the arc and the current flowing through it depends upon whether the arc is in the steady state corresponding to the current flowing or whether the current has been changed without giving time to the vapor column and electrodes to accommodate themselves to the new strength of current. Let v be the drop of potential across an arc, and i be the current flowing. If the current be increased at a rate rapid enough that a steady state is not set up, then $\frac{dv}{di}$ is the resistance of the arc to the rapidly changing current. Throughout ordinary ranges of frequency (less than 100 kc) the ratio $\frac{dv}{di}$ is negative. Thus the alternating-current resistance of an arc is negative and is a function of the current.

26. CORONA

When the voltage between two conductors becomes sufficiently great, the electric field, which is greatest at the surface, ionizes the air at the surfaces of the conductor. The increase in the conductivity of the air or other gas surrounding the conductor is equivalent to an increase in the effective diameter of the conductor to the value at which the decreasing electric field is balanced by the dielectric strength of the air. The phenomenon is known as *corona*. When the corona is formed, there is visible a faint violet light near the conductor. If the voltage is raised, a *brush discharge* occurs in which bluish streaks like the bristles of a brush are visible near the surface of the conductor. If the voltage is still further increased, a disruptive spark discharge takes place between conductors.

In transmission lines (q.v.), corona is accompanied by power losses frequently of serious proportions. It can be controlled by the use of larger-diameter conductors and by operating with voltages low enough to prevent its formation.

The current leaving the line as corona is a function of the instantaneous voltage on the line and therefore introduces non-linearity into the network.

27. VARIABLE INDUCTANCE

The electromotive force produced by electromagnetic induction in a closed circuit having no sliding contacts is

$$e_1 = \frac{d\lambda_1}{dt} \tag{9}$$

in which λ_1 is the total flux linkages in the circuit. The flux linkages λ_1 will in general be produced by the current in the given circuit, by the currents in neighboring circuits, and by permanent magnets in the vicinity of the given circuit. The flux linkages may change, owing to changes in the currents or to motion. If there is motion the space coordinates giving the relative positions of the circuits and magnets in the group are functions of time and can be eliminated in the expression for λ. Hence λ_1 may be written

$$\lambda_1 = \lambda_1(i_1, i_2, \ldots, i_n, t) \tag{10}$$

where i_1 is the current in the circuit under consideration, $i_2, \ldots, i_n$ are the currents in neighboring circuits, and t is the time.

It follows that

$$e = \frac{\partial \lambda_1}{\partial i_1}\frac{di_1}{dt} + \frac{\partial \lambda_1}{\partial i_2}\frac{di_2}{dt} + \ldots + \frac{\partial \lambda_1}{\partial t} \tag{11}$$

The coefficient of $\frac{di_1}{dt}$ in this expression for the emf is called the *coefficient* of *self-induction* or simply the *inductance* of the circuit.

The coefficient of $\frac{di_n}{dt}$ in this expression for the emf is called the *coefficient* of *mutual induction* or simply the *mutual inductance* of the nth mesh with respect to the first.

There result the following definitions:

The *self-inductance* of a given circuit is the factor L by which the rate of increase of current in that circuit must be multiplied to give the induced electromotive force in that circuit when at rest, the currents in all neighboring circuits being zero.

The *mutual inductance* of a given circuit with respect to a second circuit is the factor M by which the rate of increase of current in the first circuit must be multiplied to give the induced electromotive force in the second circuit when these circuits are at rest, the currents in the second and all neighboring circuits being zero.

In terms of these definitions the general expression for the induced emf is

$$e_1 = L_1\frac{di_1}{dt} + M_{12}\frac{di_2}{dt} + M_{13}\frac{di_3}{dt} + \ldots + M_{1n}\frac{di_n}{dt} + \frac{\partial \lambda_1}{\partial t} \tag{12}$$

There are several special cases which arise in practical problems, each of which will be considered separately.

(*a*) *If λ_1 is a function of i_1 only* (as in an isolated iron-cored choke coil at rest),

$$\frac{\partial \lambda_1}{\partial t} = \frac{di_2}{dt} = \frac{di_3}{dt} = \ldots = \frac{di_n}{dt} = 0$$

from which it follows that

$$e_1 = L_1\frac{di_1}{dt} \tag{13}$$

If the permeance of the core is constant L is a constant; in general, however, L will be a function of the current i_1.

(*b*) *If* λ_1 *is a function of* i_n *only* (as in an open winding of a multi-winding transformer in which another winding carries current),

$$\frac{\partial \lambda_1}{\partial t} = \frac{di_1}{dt} = \frac{di_2}{dt} = \ldots = \frac{di_{n-1}}{dt} = 0$$

from which it follows that
$$e_1 = M_{1n} \frac{di_n}{dt} \tag{14}$$

If the permeance of the core is constant M_{1n} is a constant; in general, however, M will be a function of the current i_n.

(*c*) *If* λ_1 *is composed of a sum of terms each of which is directly proportional to one of the currents*, and is also a function of t (as when several circuits move with respect to each other but have constant permeances, for example, an air-core alternator)

$$\lambda_1 = i_1 A_1 (t) + i_2 A_{12} (t) + \ldots + i_n A_{1n} (t) \tag{15}$$

The electromotive force is, from eq. (11),

$$e_1 = A_1 (t) \frac{di_1}{dt} + A_{12} (t) \frac{di_2}{dt} + \ldots + A_{1n} (t) \frac{di_n}{dt} \tag{16}$$
$$+ \frac{\partial}{\partial t} [i_1 A_1 (t) + i_2 A_{12} (t) + \ldots + i_n A_{1n} (t)]$$

and comparing coefficients with eq. (12) it is seen that

$$\begin{aligned} A_1 (t) &= L_1 \\ A_{12} (t) &= M_{12} \\ A_{1n} (t) &= M_{1n} \end{aligned} \tag{17}$$

and

hence

$$e_1 = L_1 \frac{di_1}{dt} + M_{12} \frac{di_2}{dt} + \ldots + M_{1n} \frac{di_n}{dt} + i_1 \frac{dL_1}{dt} + i_2 \frac{dM_{12}}{dt} + \ldots + i_n \frac{dM_{1n}}{dt} \tag{18}$$

Eq. (18) may be written

$$e_1 = \frac{d}{dt} (L_1 i_1 + M_{12} i_2 + M_{13} i_3 + \ldots + M_{1n} i_n) \tag{19}$$

Eq. (19) holds when the self and mutual inductances are functions of t only, but does not hold when they are functions of the current. In other words, eq. (19) may be used for generator and motor calculations if the magnetization curve can be assumed to be linear; whereas, for calculations when the magnetization curve cannot be assumed to be straight (even in the case of a transformer), eq. (12) must be used.

28. SPECIAL MATHEMATICAL METHODS

There is no general method of solution applicable to differential equations which are not linear. Therefore the electric circuit equations arising from non-linear circuits are not capable of solution by any standard scheme. Various special methods, satisfactory for limited classes of problems, have been devised, some of which are outlined in this article. The methods may be classified as follows:

REDUCTION OF THE NETWORK EQUATIONS TO APPROXIMATE LINEAR EQUATIONS. In many circuits the non-linearity is in the nature of a second order effect. In such circuits it is desirable to solve for those currents which would flow if the network were linear, and to superimpose upon them correction currents to take account of the non-linearity. An excellent example of this is the iron-core transformer which is given in some detail in Art. 29. The method of solution outlined in that article may be applied to any circuit falling in this classification.

SUBSTITUTION OF AN EMF FOR THE NON-LINEAR ELEMENT. If the non-linearity consists in the sudden opening or closing of a circuit the currents may be found by making use of the two principles:

(*a*) The effect at any succeeding instant of time of a short circuit at time $t = 0$ is precisely the same as the insertion at $t = 0$ of a voltage $-v(t)$, equal and opposite to the voltage $v(t)$ which exists at that instant across the terminals to be short-circuited.

The resultant currents are therefore composed of two components: the currents which would exist in the invariable network in the absence of the short circuit and the currents due to the emf $v(t)$ inserted at $t = 0$. Both these components are calculable by usual methods.

(*b*) The effects at any succeeding instant of time of opening a branch of a network at

time $t = 0$ is the same as the insertion at $t = 0$ of a voltage $v(t)$ which produces in the branch to be opened a current $-i(t)$ equal and opposite to the current $i(t)$ which would exist in the branch in the absence of the open circuit.

The resultant currents are therefore composed of two components: the currents which would flow in the network in the absence of the open circuit and the currents which flow due to the emf $v(t)$ inserted at $t = 0$. Both these components are calculable by usual methods.

In a network having a non-linear circuit element, the mesh equation for the mesh involving this element is

$$Z(p)i + \phi(i) = e(t) \tag{20}$$

in which $Z(p)$ is the operational impedance of the linear part of the mesh, $\phi(i)$ is the voltage drop across the non-linear circuit element, and $e(t)$ is the impressed emf in the mesh.

If this equation is rewritten as

$$Z(p)i = e(t) - \phi[i(t)] \tag{20a}$$

it is possible to solve formally for the current by treating the right-hand member as the impressed voltage. Hence

$$i(t) = \frac{d}{dt}\int_0^t h(t-\lambda)\{e(\lambda) - \phi[i(\lambda)]\}d\lambda \tag{21}$$

which may be written

$$i(t) = i_0(t) - \frac{d}{dt}\int_0^t h(t-\lambda)\phi[i(\lambda)]d\lambda \tag{21a}$$

in which $i_0(t) =$ the current which would flow in the invariable part of the circuit due to $e(t)$; $h(t) =$ the indicial admittance of the invariable part.

This is an integral equation which can be solved in general only in the form of an infinite series. For methods of solution see Lovitt, Linear Integral Equations, McGraw-Hill Book Co.

SUCCESSIVE APPROXIMATIONS, NUMERICAL INTEGRATION. When the non-linear differential equations for the currents in a non-linear network are written down their exact solution becomes a purely mathematical problem. The process of obtaining an infinite series solution by successive approximations is given in any standard text on differential equations. For the numerical integration of differential equations refer to Runge and König, Numerisches Rechnen, Julius Springer, 1924. These methods are usually very laborious and should be avoided if possible.

A method of solution of non-linear differential equations of the particular type found in vacuum-tube problems was developed by Carson. (See Bibliography and Vol. 5, Electric Circuits, Lines, and Fields.) This method is based on a Taylor's series expansion and is of great practical value to the communication engineer. It is not easily extended to other problems.

Another special scheme which has been applied to non-linear communication problems is the *isoclyne* method. This method involves the plotting of families of curves using the derivative as a parameter; it has been used by Van der Pol in the analysis of relaxation oscillators.

THE DIFFERENTIAL ANALYZER. Perhaps the most powerful tool available for the numerical solution of non-linear circuit problems is a machine called the differential analyzer. This device is capable of solving mechanically differential equations in which the coefficients are functions of the dependent variables. The solution may be obtained in the form of a plotted curve or in tabular form, the latter giving the greater accuracy. The precision is adequate for all engineering purposes. Two such machines are at present available in this country, one at the Massachusetts Institute of Technology and one at the Moore School of Electrical Engineering, University of Pennsylvania. For a complete description of its principle of operation see V. Bush, The differential analyzer, *Journal Franklin Institute,* Vol. 212, No. 4, October, 1931.

29. IRON-CORED TRANSFORMERS

The mesh equations of a two-winding transformer upon the primary of which is impressed a voltage v_1, and which supplies a voltage v_2 to a receiver connected to its secondary, are:

$$r_1 i_1 + L_1 \frac{di_1}{dt} - M\frac{di_2}{dt} = v_1 \tag{22}$$

$$r_2 i_2 + L_2 \frac{di_2}{dt} - M\frac{di_1}{dt} = -v_2 \tag{22a}$$

in which i_1 and i_2 are the primary and secondary mesh currents. Owing to the variable permeability of the iron core the values of the inductances depend upon the currents. The equations are therefore non-linear and cannot be solved by ordinary means. In the design of power transformers for usual purposes, an attempt is made to keep the leakage as small as possible, whereas the mutual inductance is made relatively large. This fact makes possible an approximate method of solution which yields results sufficiently accurate for most practical purposes.

The self-inductances of the windings may be expressed in terms of the leakage and mutual inductances:

$$L_1 = L_1' + a\,M \tag{23}$$

$$L_2 = L_2' + \frac{M}{a} \tag{23a}$$

in which L_1' and L_2' are the primary and secondary leakage inductances and a is the turn ratio. L_1' and L_2' are constants and are quite small in comparison to M. Substitution of eqs. (23) and (23a) in eqs. (22) and (22a) gives the following mesh equations.

$$aM\frac{d}{dt}\left(i_1 - \frac{i_2}{a}\right) = v_1 - r_1 i_1 - L_1'\frac{di_1}{dt} \tag{24}$$

$$M\frac{d}{dt}\left(i_1 - \frac{i_2}{a}\right) = v_2 + r_2 i_2 + L_2'\frac{di_2}{dt} \tag{24a}$$

It is apparent that if r_1 and L_1' are small the right-hand side of eq. (24) does not differ greatly in wave form from v_1. Hence the quantity $M\frac{d}{dt}\left(i_1 - \frac{i_2}{a}\right)$ does not differ greatly in wave form from v_1. It should be noted that, since M is variable, the quantity $\left(i_1 - \frac{i_2}{a}\right)$ may be considerably different in wave form from v_1. The secondary current i_2 will be essentially the same in wave form as v_1 since the term $M\frac{d}{dt}\left(i - \frac{i_2}{a}\right)$ may be thought of as an electromotive force impressed upon a linear mesh in which the impedance drop is

$$v_2 + r_2 i_2 + L_2'\frac{di_2}{dt}$$

The primary current can thus be treated as the sum of two components $\left(\frac{i_2}{a}\right)$ and $\left(i_1 - \frac{i_2}{a}\right)$, the first component having essentially the same wave shape as the impressed voltage, and therefore representable as a current flowing in an equivalent linear network, and the second component being distorted in wave shape and representing the non-linear effect of the transformer. The first component $\left(\frac{i_2}{a}\right)$ is often called the load component of the primary current; the second component $\left(i_1 - \frac{i_2}{a}\right)$ is called the magnetizing or exciting current of the transformer.

The scheme used in eqs. (24) and (24a) of splitting mesh equations into two parts, one containing all the non-linearity and the other being entirely linear, is extremely useful in problems involving iron cores, especially electrical machines.

If the core of a transformer is conducting, as it always is in practical cases, there are an infinite number of conducting paths, each having mutual inductances with respect to the primary and secondary. The currents flowing in these paths are called eddy currents.

Let M_{1i} be the mutual inductance between the ith eddy-current path and the primary winding, and let M_{2i} be the mutual inductance between the ith eddy-current path and the secondary winding. If, as in eqs. (22) and (22a) we take M_{12} with a negative sign, then M_{1i} and M_{2i} must have opposite signs.

Adopt the convention that all the M_{1i}'s have negative signs, then all the M_{2i}'s have positive signs. The mesh equations for the primary and secondary currents (neglecting non-linearity of the core) are

$$(r_1 + j\omega L_1)I_1 - j\omega M_{12} I_2 - j\omega \sum_{i=3}^{\infty} M_{1i} I_i = V_1 \tag{25}$$

$$(r_2 + j\omega L_2)I_2 - j\omega M_{12} I_1 + j\omega \sum_{i=3}^{\infty} M_{2i} I_i = -V_2 \tag{26}$$

Corresponding to the eddy-current paths there will exist an infinite number of equa-

tions. If in these the terms involving I_1 and I_2 are transposed to the right-hand side it is possible, at least formally, to solve for each of the currents I_i in terms of I_1 and I_2. If these values are then substituted back in eqs. (25) and (26), two equations will result which involve only parameters of the network and the currents I_1 and I_2. These are the equations of an equivalent T network, in which the quantity multiplying I_2 in the first equation will be the same as the quantity multiplying I_1 in the second equation. This quantity will be a complex number, both real and imaginary parts of which are functions of the frequency ω.

Making the assumptions (*a*) that the resistance of a given eddy-current path is large in comparison with its inductance, (*b*) that the mutual inductance between an eddy-current path and either the primary or secondary is large in comparison with the mutual inductance between two eddy-current paths, and (*c*) that the leakage is small, the mesh equations for the primary and secondary currents become

$$(r_1 + j\omega L_1')\, I_1 + a(r_e + j\omega M_{12})\left(I_1 - \frac{I_2}{a}\right) = V_1 \tag{27}$$

$$(r_2 + j\omega L_2')\, I_2 - (r_e + j\omega M_{12})\left(I_1 - \frac{I_2}{a}\right) = -V_2 \tag{28}$$

in which L_1' and L_2' are the primary and secondary leakage inductances, a is the turn ratio, and r_e is a resistance representing the effect of the eddy currents. The resistance r_e is proportional to the square of the frequency of the impressed voltage.

POLYPHASE SYSTEMS AND SYMMETRICAL COMPONENTS

30. POLYPHASE CURRENTS AND VOLTAGES

The term polyphase alternating voltages is applied to the voltages of a group in which the modulus values are approximately the same and in which the difference in phase between successive voltages in the group is approximately equal to 2π divided by the number of voltages in the group. If these conditions are exactly instead of only approximately true, the voltages are said to be *balanced* polyphase voltages. If these conditions are not even approximately true the voltages are still termed polyphase voltages (but badly unbalanced) if they arise in a system in which the normal or ideal voltages are polyphase.

Polyphase currents are defined in the same way as polyphase voltages.

A polyphase circuit is a circuit in which the normal or ideal currents are polyphase currents. Thus a circuit having three meshes may be a three-phase circuit or not, depending upon its use.

31. MESH AND STAR CONNECTIONS

Consider n separate coils or windings, which may be mounted on a common armature or be entirely distinct, as for example n groups of lamps. When these n windings are connected end to end so that they are all in series, forming a closed chain, as in Fig. 1, and terminals are brought out from the n junctions, they are said to be connected in *mesh*. When one terminal of each of these windings is connected to a common junction point,

as in Fig. 2, and terminals are brought out from the free ends, the windings are said to be connected in *star*, and the common point is called the *neutral point*.

When such a group of n windings, as shown in Fig. 1 or 2, is connected to a generator or other source of emf having n separate windings and therefore developing n different emf's which differ in phase from one another, the system is called an n-phase system, each winding being called a *phase*. For example, when there are three separate windings on

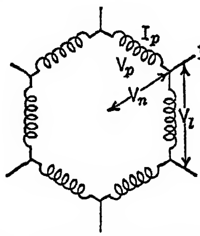

FIG. 1. Mesh Connected Network

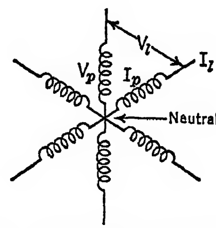

Fig. 2. Star Connected Network

the generator, three line wires and three windings constituting the load, the system is a three-phase system.

A system is said to be balanced if the phase impedances are equal and the impressed voltages are balanced.

32. PHASE AND LINE CURRENTS AND VOLTAGES

The current I_p in any winding or phase of an n-phase system, see Figs. 1 and 2, is called the *phase current*, and the drop (or rise) of potential V_p through this winding is called the *phase voltage*. The current I_l in the line leaving any terminal of an n-phase system is called the *line current*, and the voltage V_l between adjacent line wires or terminals is called the *line voltage*, except in the special case of a two-phase connection (see below) when the voltage between diametrically opposite terminals is called the line voltage. In the case of a star connection the voltage between any terminal and the neutral point is called the *voltage to neutral*; in the case of a balanced mesh connection, by voltage to neutral is meant the voltage which would exist between any terminal and the neutral of a star connection connected to the terminals of the actual device, the impedance of all the legs of the star connection forming this *artificial neutral* being equal and sufficiently large not to take an appreciable current.

The relations between these various currents and voltages for a balanced n-phase system are as follows:

	Mesh	Star
Number of phases	n	n
Line current	I_l	I_l
Line voltage	V_l	V_l
Phase current	$I_p = \dfrac{1}{2 \sin \frac{\pi}{n}} I_l$	$I_p = I_l$
Phase voltage	$V_p = V_l$	$V_p = \dfrac{1}{2 \sin \frac{\pi}{n}} V_l$
Voltage to neutral	$V_n = \dfrac{1}{2 \sin \frac{\pi}{n}} V_p$	$V_n = V_p$
Total volt-amperes	$nV_p I_p = \dfrac{n}{2 \sin \frac{\pi}{n}} V_l I_l$	$nV_p I_p = \dfrac{n}{2 \sin \frac{\pi}{n}} V_l I_l$

33. POWER IN POLYPHASE SYSTEMS

The total power in any polyphase system is the sum of the powers in the separate phases of the system. Thus for an unbalanced n-phase system the total average power is

$$P = \sum_{k=1}^{n} V_k I_k \cos\theta_k \tag{1}$$

in which θ_k is the phase power factor of the kth phase and V_k and I_k are the phase voltage and current respectively of that phase. This is true for either a star or a mesh connection.

In the special case of a balanced n-phase system the power may be expressed as

$$P = nV_p I_p \cos\theta_p = \frac{nV_l I_l \cos\theta_p}{2\sin\frac{\pi}{n}} \tag{2}$$

Note that even when the power is expressed in terms of line voltages and currents the power factor is the phase power factor.

34. TWO-PHASE (OR QUARTER-PHASE) SYSTEM

Strictly, the so-called single-phase system is a star-connected two-phase system, since the currents from the two terminals are in opposite directions at any instant, the current leaving by one and entering by the other. However, in practice the name two-phase system is used for a system supplied from a generator or other source of emf having two windings in which are developed two emf's differing in phase by 90 deg; i.e., a two-phase system is in reality two distinct single-phase systems each with two terminals. Two of the four terminals may be connected to each other, in which case but three line wires are required. Or the two single-phase systems may be connected at their middle points; in this case the two-phase system may be considered as a four-phase, or, as it is usually called, a "quarter-phase" system.

35. THREE-PHASE SYSTEM, DELTA AND WYE CONNECTIONS

For a three-phase system the generators and motors are designed with three windings or phases which may be connected either in mesh, usually called a *delta connection* since the diagram of the three windings forms a Greek delta, or in star, usually called a *wye connection* since the diagram of the three windings forms a Y. The relations between line and phase currents and voltages for a balanced three-phase system are as follows:

	Delta	Y
Line current	I_l	I_l
Line voltage	V_l	V_l
Phase current	$I_p = \frac{I_l}{\sqrt{3}}$	$I_p = I_l$
Phase voltage	$V_p = V_l$	$V_p = \frac{V_l}{\sqrt{3}}$
Voltage to neutral	$V_n = \frac{V_l}{\sqrt{3}}$	$V_n = V_p$
Total volt-amperes	$3V_p I_p = \sqrt{3}V_l I_l$	$3V_p I_p = \sqrt{3}V_l I_l$
Phase power factor	$\cos\theta_p$	$\cos\theta_p$
Total power	$\sqrt{3}V_l I_l \cos\theta_p$	$\sqrt{3}V_l I_l \cos\theta_p$

As was pointed out in Art. 20 any network having n points of entry can be completely represented by a network having n points of entry in which each point is connected by an impedance to every other point. If $n = 3$ the equivalent network is a delta. Hence any wye, balanced or unbalanced, may be transformed into an equivalent delta. The inverse transformation also exists. The transformation formulas are given by

$$Z_1 = \frac{Z_{31}Z_{12}}{Z_{12} + Z_{23} + Z_{31}}$$

$$Z_2 = \frac{Z_{12}Z_{23}}{Z_{12} + Z_{23} + Z_{31}}$$

$$Z_3 = \frac{Z_{23} Z_{31}}{Z_{12} + Z_{23} + Z_{31}}$$

$$Z_{12} = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_3 Z_1}{Z_3}$$

$$Z_{23} = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_3 Z_1}{Z_1}$$

$$Z_{31} = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_3 Z_1}{Z_2}$$

In which Z_1, Z_2, and Z_3 are the wye impedances from lines 1, 2, and 3 to neutral and Z_{12}, Z_{23}, Z_{31} are the delta impedances between lines 1 and 2, 2 and 3, and 3 and 1.

36. BALANCED THREE-PHASE CIRCUITS

Any problem in regard to a *balanced* three-phase circuit may be solved by reducing all parts of the circuit to an equivalent Y connection, provided the currents and emf's are sine waves. The transformations are made as follows:

Any Δ-connected motor or generator is considered as equivalent to a Y-connected generator or motor in which

$$E_y = \frac{E_\Delta}{\sqrt{3}}, \quad r_y = \frac{r_\Delta}{3}, \quad x_y = \frac{x_\Delta}{3}$$

where the quantities E_y, r_y, and x_y are the emf, resistance, and reactance per phase of the Y-connected machine equivalent to the emf, resistance, and reactance per phase of the actual Δ-connected machine.

Each of the line wires is in series with a corresponding phase of the equivalent Y-connected machine.

When all parts of the circuit have thus been reduced to equivalent Y's, each of the three phases may be treated as a single-phase circuit, each circuit considered completed by a wire having zero impedance connecting all the neutrals together, since all the neutrals are at the same potential.

The voltages thus calculated are the voltages to neutral, and the currents are line currents. To find the line voltage multiply the calculated voltage by $\sqrt{3}$; similarly, to find the actual phase current in the Δ-connected generator or load divide the calculated current by $\sqrt{3}$.

37. SYMMETRICAL COMPONENTS OF CURRENTS AND VOLTAGES

The general solution of unbalanced polyphase networks presents a very formidable problem when attacked by the method of ordinary mesh equations. It was discovered independently by Stokvis and Fortescue that the equations for such problems often exhibited a striking symmetry, and that a general method could be developed which had peculiar advantages when applied to certain types of unbalanced polyphase networks, in particular those involving rotating machines. The outstanding feature of this method consists in a choice of suitable symmetrical systems of vectors in terms of which to formulate the problem. This procedure is analogous to the selection of normal coordinates in certain physical problems, a process which has proved extremely fruitful. The method is capable of considerable generalization, but for the sake of simplicity the three-phase system only will be given.

It should be pointed out here that, for ordinary networks which have no moving parts, and which therefore give rise to differential equations having constant coefficients, the method of symmetrical components has no advantages unless the network is partly symmetrical and partly unsymmetrical. If, however, the network has one portion which is symmetrical and one portion which is unsymmetrical, as, for example, an unbalanced load connected to a symmetrical transmission line fed by a symmetrical generator, a considerable simplification is obtained by the use of symmetrical components. In rotating machines, as is demonstrated in the chapter on Electrical Machines, the advantages of the symmetrical component method are even greater.

The complex number representing one of the cube roots of unity will be of importance in this analysis. Let the complex number $e^{j(2\pi/3)}$ be designated by

$$a = e^{j(2\pi/3)} = {}^1/_2(-1 + j\sqrt{3}) \qquad (3)$$

then it follows that

$$a^2 = e^{j(4\pi/3)} = 1/2\,(-1 - j\sqrt{3}) \tag{4}$$

and that

$$a^3 = 1 \tag{5}$$

Note also that

$$1 + a + a^2 = 0 \tag{6}$$

The following are identities, in which A, B, and C are three arbitrary (complex or real) quantities, and may be readily verified:

$$A = \frac{A + B + C}{3} + \frac{A + aB + a^2 C}{3} + \frac{A + a^2 B + a^4 C}{3} \tag{7}$$

$$B = \frac{A + B + C}{3} + \frac{1}{a}\frac{A + aB + a^2 C}{3} + \frac{1}{a^2}\frac{A + a^2 B + a^4 C}{3} \tag{8}$$

$$C = \frac{A + B + C}{3} + \frac{1}{a^2}\frac{A + aB + a^2 C}{3} + \frac{1}{a^4}\frac{A + a^2 B + a^4 C}{3} \tag{9}$$

By writing eq. (7) in the form

$$A = 1/3(1 + 1 + 1)A + 1/3(1 + a + a^2)B + 1/3(1 + a^2 + a)C$$

these relations follow immediately from eq. (6).

If the quantities A, B, and C are complex numbers they may be represented by vectors. Eqs. (7), (8), and (9) may therefore be regarded as the vector equations for A, B, and C in terms of certain components chosen in a particular manner. Note that the three first components of A, B, and C are the same, that the three second components differ from each other only by factors which are powers of a, and that the three last components also differ from each other only by factors which are powers of a.

Let these components be denoted by the letters with subscripts 0, 1, and 2.

$$\left.\begin{aligned} A &= A_0 + A_1 + A_2 \\ B &= B_0 + B_1 + B_2 \\ C &= C_0 + C_1 + C_2 \end{aligned}\right\} \tag{10}$$

where the nine complex quantities on the right-hand side are defined by

$$A_0 = B_0 = C_0 = \frac{A + B + C}{3} \tag{11}$$

$$A_1 = aB_1 = a^2 C_1 = \frac{A + aB + a^2 C}{3} \tag{11a}$$

$$A_2 = a^2 B_2 = aC_2 = \frac{A + a^2 B + aC}{3} \tag{11b}$$

The group (A_0, B_0, C_0) consists of three coincident vectors, while each of the groups (A_1, B_1, C_1) and (A_2, B_2, C_2) consists of a symmetrical three-phase set. The nine vectors on the right-hand sides of eqs. (11) are therefore called the *symmetrical components* of the original vectors. The vectors A_0, B_0, C_0 are called the *zero sequence* components; the vectors A_1, B_1, and C_1 are called the *positive sequence* components; and the vectors A_2, B_2, and C_2, the *negative sequence* components.

If the three complex quantities A, B, and C denote sine-wave electrical quantities by the usual complex number notation for linear electric circuits, then all the symmetrical components of these complex numbers will represent component electrical quantities. Since superposition holds in all problems in which the ordinary complex number notation can be used, the symmetrical component transformation yields actual electrical quantities which can be used in the solution of network problems. That is, any problem may be solved for the various components separately and the result obtained by addition. For example, it may be that the complex numbers represent currents having an angular velocity ω, in which case the positive sequence components will have the form

$$\left.\begin{aligned} &A_1 = Ie^{j\phi} \text{ which corresponds to } \sqrt{2}I \cos(\omega t + \phi) \\ &B_1 = a^2 A_1 = Ie^{j\phi} e^{j(4\pi/3)} \text{ which corresponds to } \sqrt{2}I \cos(\omega t + \phi - 120°) \\ &C_1 = aA_1 = Ie^{j\phi} e^{j(2\pi/3)} \text{ which corresponds to } \sqrt{2}I \cos(\omega t + \phi - 240°) \end{aligned}\right\} \tag{12}$$

This illustration gives the justification for calling the vectors having the subscript 1 positive sequence vectors, i.e., these vectors when used in electric circuits will represent time functions such that A_1 precedes B_1 which precedes C_1 in time.

38. GRAPHICAL CALCULATION OF SYMMETRICAL COMPONENTS

Eq. (7) suggests a simple geometrical construction for the determination of the symmetrical components of three vectors A, B, and C. The sum of A, B, and C, is $3A_0$. If B be rotated through a positive angle of 120 deg and C be rotated through a positive angle of 240 deg and the resulting vectors added to A the resultant is $3A_1$. If B be rotated through a negative angle of 120 deg and C be rotated through a negative angle of 240 deg and the resulting vectors added to A the resultant is $3A_2$. The graphical representation is shown in Fig. 3.

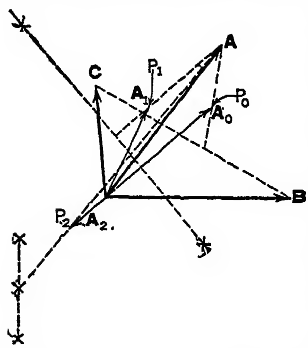

FIG. 3. Construction of Symmetrical Components of Three Arbitrary Complex Quantities

In the construction of Fig. 3, use is made of the theorem of geometry which states that one-third the resultant of three vectors is a vector from the origin to the centroid of the triangle whose vertices lie at the ends of the three vectors. Thus the vector A_0 is OP_0 where P_0 is the centroid of the triangle ABC. The point P_0 is located two-thirds the distance from A along a line from A to the midpoint of BC. The points of P_1 and P_2 are located in a similar manner after rotating the vectors B and C through the appropriate angles.

Having gotten the symmetrical components of the vector A with respect to B and C, it is a simple matter to obtain the symmetrical components of B and C. Eqs. (11) give the necessary information for this construction, viz.: B_0 and C_0 are coincident with A_0, B_1 is equal in modulus to A_1 and displaced from it in a counter-clockwise direction by an angle of 240 deg, B_2 is equal in modulus to A_2 and displaced from it in a counter-clockwise direction by an angle of 120 deg, etc.

39. SYMMETRICAL COMPONENTS OF IMPEDANCES

A network consisting of three impedances Z_1, Z_2, and Z_3 connected in *wye* gives the following equations in terms of phase currents and phase voltages

$$\left.\begin{aligned} Z_1 I_1 &= V_1 \\ Z_2 I_2 &= V_2 \\ Z_3 I_3 &= V_3 \end{aligned}\right\} \tag{13}$$

which in terms of symmetrical components are

$$\left.\begin{aligned} Z_1 (I_{10} + I_{11} + I_{12}) &= V_{10} + V_{11} + V_{12} \\ Z_2 (I_{20} + I_{21} + I_{22}) &= V_{20} + V_{21} + V_{22} \\ Z_3 (I_{30} + I_{31} + I_{32}) &= V_{30} + V_{31} + V_{32} \end{aligned}\right\} \tag{14}$$

From eqs. (11) the following relations hold

$$\begin{aligned} V_{10} &= V_{20} = V_{30} & I_{10} &= I_{20} = I_{30} \\ V_{21} &= a^2 V_{11} & I_{21} &= a^2 I_{11} \\ V_{31} &= aV_{11} & I_{31} &= aI_{11} \\ V_{22} &= aV_{12} & I_{22} &= aI_{12} \\ V_{32} &= a^2 V_{12} & I_{32} &= a^2 I_{12} \end{aligned}$$

hence eqs. (14) may be written

$$\left.\begin{aligned} Z_1 (I_{10} + I_{11} + I_{12}) &= V_{10} + V_{11} + V_{12} \\ Z_2 (I_{10} + a^2 I_{11} + aI_{12}) &= V_{10} + a^2 V_{11} + aV_{12} \\ Z_3 (I_{10} + aI_{11} + a^2 I_{12}) &= V_{10} + aV_{11} + a^2 V_{12} \end{aligned}\right\} \tag{15}$$

Adding eqs. (15)

$$\frac{Z_1 + Z_2 + Z_3}{3} I_{10} + \frac{Z_1 + a^2 Z_2 + aZ_3}{3} I_{11} + \frac{Z_1 + aZ_2 + a^2 Z_3}{3} I_{12} = V_{10}$$

Multiplying the three equations of (15) by 1, a, and a^2 respectively and adding

$$\frac{Z_1 + aZ_2 + a^2 Z_3}{3} I_{10} + \frac{Z_1 + Z_2 + Z_3}{3} I_{11} + \frac{Z_1 + a^2 Z_2 + aZ_3}{3} I_{12} = V_{11}$$

Multiplying the three equations of (15) by 1, a^2, and a respectively and adding there results:

$$\frac{Z_1 + a^2 Z_2 + aZ_3}{3} I_{10} + \frac{Z_1 + aZ_2 + a^2 Z_3}{3} I_{11} + \frac{Z_1 + Z_2 + Z_3}{3} I_{12} = V_{12}$$

Hence the following equations may be written

$$\left.\begin{aligned} Z_{10} I_{10} + Z_{12} I_{11} + Z_{11} I_{12} &= V_{10} \\ Z_{11} I_{10} + Z_{10} I_{11} + Z_{12} I_{12} &= V_{11} \\ Z_{12} I_{10} + Z_{11} I_{11} + Z_{10} I_{12} &= V_{12} \end{aligned}\right\} \qquad (16)$$

in which the Z's are symmetrical components of the impedances Z_1, Z_2, and Z_3, and are defined by equations similar to eqs. (10).

It should be pointed out that the Z's of eqs. (16) are symmetrical components of impedances in a purely formal sense, and that no particular physical significance can be attached to them. In certain electric circuits in which the parameters are functions of time, in particular in rotating machines, it is possible to obtain equivalent impedances which have different values depending upon whether the currents flowing through them have positive or negative phase sequence. The *positive* (negative, zero) *sequence impedance* in this sense has an important physical significance and is not related to the above defined *positive* (negative, zero) *sequence impedance*. Care should be taken to keep the two concepts distinct; the context will usually leave no doubt as to which is meant. See the chapter on Electrical Machines.

40. MATRIX* FORMULATION OF THE THREE-PHASE PROBLEM

It is convenient, in the development of circuit equations in terms of the symmetrical components of currents, voltages, and impedances, to make use of the algebra of matrices.

The properties of the particular matrix S defined by eq. (17), and designated by the term *sequence matrix*, are used.

$$S = {}^1/_3 \begin{vmatrix} 1 & 1 & 1 \\ 1 & a & a^2 \\ 1 & a^2 & a \end{vmatrix} \qquad (17)$$

Consider the product of any arbitrary square matrix having three rows and columns by the matrix S.

Let the arbitrary matrix (in which the elements are complex numbers) be

$$R = \begin{vmatrix} A & D & G \\ B & E & H \\ C & F & K \end{vmatrix} \qquad (18)$$

Then the product matrix is

$$SR = {}^1/_3 \begin{vmatrix} (A + B + C) & (D + E + F) & (G + H + K) \\ (A + aB + a^2 C) & (D + aE + a^2 F) & (G + aH + a^2K) \\ (A + a^2 B + aC) & (D + a^2 E + aF) & (G + a^2 H + aK) \end{vmatrix} \qquad (19)$$

and in terms of the symmetrical components of the elements of the matrix R taken in the grouping (A, B, C); (D, E, F); (G, H, K) the matrix SR becomes

$$SR = \begin{vmatrix} A_0 & D_0 & G_0 \\ A_1 & D_1 & G_1 \\ A_2 & D_2 & G_2 \end{vmatrix} \qquad (20)$$

in which A_0 is the zero sequence component of A with respect to B and C, A_1 is the positive sequence component of A with respect to B and C, etc. Thus multiplication of a given matrix by S has the effect of replacing the elements in any column of the given matrix by the symmetrical components of the leading element of the column taken with respect to the other two elements of that column.

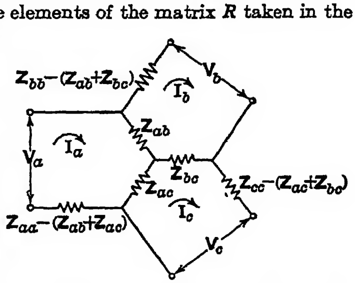

FIG. 4. General Three-phase Network

Suppose that it is desired to solve the network shown in Fig. 4 in terms of symmetrical components. The mesh equations are:

$$\left.\begin{aligned} Z_{aa} I_a - Z_{ab} I_b - Z_{ac} I_c &= V_a \\ -Z_{ab} I_a + Z_{bb} I_b - Z_{bc} I_c &= V_b \\ -Z_{ac} I_a - Z_{bc} I_b + Z_{cc} I_c &= V_c \end{aligned}\right\} \qquad (21)$$

* For the algebra of matrices refer to Bôcher, Introduction to Higher Algebra.

This set of equations may be written down as a group by means of the matrix equation

$$ZI = V \tag{21a}$$

where the matrices Z, I, and V are defined by

$$Z = \begin{vmatrix} Z_{aa} & -Z_{ab} & -Z_{ac} \\ -Z_{ab} & Z_{bb} & -Z_{bc} \\ -Z_{ac} & -Z_{bc} & Z_{cc} \end{vmatrix}$$

$$I = \begin{vmatrix} I_a & 0 & 0 \\ I_b & 0 & 0 \\ I_c & 0 & 0 \end{vmatrix}$$

and

$$V = \begin{vmatrix} V_a & 0 & 0 \\ V_b & 0 & 0 \\ V_c & 0 & 0 \end{vmatrix}$$

Let both sides of eq. (21a) be multiplied by the matrix S. Since multiplication of matrices is associative

$$(SZ)I = (SV) \tag{22}$$

which contains on the right-hand side the symmetrical components of voltages, which is desired. Since $S^{-1}S$ is the unit matrix it follows that for any matrices P and Q

$$(P)(Q) = P(S^{-1}S)Q = (PS^{-1})(SQ) \tag{23}$$

Applying this operation to the left-hand side of eq. (22) there results

$$(SZS^{-1})(SI) = (SV) \tag{24}$$

which is a matrix equation containing symmetrical components of currents and voltages.

The inverse of the matrix S is

$$S^{-1} = \begin{vmatrix} 1 & 1 & 1 \\ 1 & a^2 & a \\ 1 & a & a^2 \end{vmatrix} \tag{25}$$

The expansion of the matrix (SZS^{-1}) may, after some rearrangement of terms, be written

$$(SZS^{-1}) = \begin{vmatrix} (Z_{aa0} - 2Z_{bc0}) & (Z_{aa2} + Z_{bc2}) & (Z_{aa1} + Z_{bc1}) \\ (Z_{aa1} + Z_{bc1}) & (Z_{aa0} + Z_{bc0}) & (Z_{aa2} - 2Z_{bc2}) \\ (Z_{aa2} + Z_{bc2}) & (Z_{aa1} - 2Z_{bc1}) & (Z_{aa0} + Z_{bc0}) \end{vmatrix} \tag{26}$$

in which the Z's are symmetrical components of impedances taken in the groupings (Z_{aa}, Z_{bb}, Z_{cc}) and (Z_{ab}, Z_{bc}, Z_{ac}). That is

$$\begin{aligned} Z_{aa0} &\equiv {}^1/_3(Z_{aa} + Z_{bb} + Z_{cc}) \\ Z_{aa1} &\equiv {}^1/_3(Z_{aa} + aZ_{bb} + a^2 Z_{cc}) \\ Z_{aa2} &\equiv {}^1/_3(Z_{aa} + a^2 Z_{bb} + aZ_{cc}) \\ Z_{bc0} &\equiv {}^1/_3(Z_{bc} + Z_{ac} + Z_{ab}) \\ Z_{bc1} &\equiv {}^1/_3(Z_{bc} + aZ_{ac} + a^2 Z_{ab}) \\ Z_{bc2} &\equiv {}^1/_3(Z_{bc} + a^2 Z_{ac} + aZ_{ab}) \end{aligned}$$

Upon expanding eq. (24) and equating corresponding elements, the following equations relating the symmetrical components of currents, voltages, and impedances result:

$$\left.\begin{aligned} (Z_{aa0} - 2Z_{bc0})\, I_{a0} + (Z_{aa2} + Z_{bc2})\, I_{a1} + (Z_{aa1} + Z_{bc1})\, I_{a2} &= V_{a0} \\ (Z_{aa1} + Z_{bc1})\, I_{a0} + (Z_{aa0} + Z_{bc0})\, I_{a1} + (Z_{aa2} - 2Z_{bc2})\, I_{a2} &= V_{a1} \\ (Z_{aa2} + Z_{bc2})\, I_{a0} + (Z_{aa1} - 2Z_{bc1})\, I_{a1} + (Z_{aa0} + Z_{bc0})\, I_{a2} &= V_{a2} \end{aligned}\right\} \tag{27}$$

The principle of superposition, which holds for any network in which the parameters are constants or functions of the time only, states that the current in any branch of a network is the sum of the currents which would be produced in this branch by the electromotive forces singly or in any arbitrary grouping. It is permissible, therefore, to solve sets of equations of the form (27) for the symmetrical components of the currents when the symmetrical components of one voltage only are applied, and to add such solutions. Hence the current I_a of eq. (21) is given by

$$I_a = I_{a0} + I_{a1} + I_{a2}$$

in which I_{a0}, I_{a1}, and I_{a2} are the solutions of (27). Similarly

$$I_b = I_{a0} + a^2 I_{a1} + aI_{a2}$$

and

$$I_c = I_{a0} + aI_{a1} + a^2 I_{a2}$$

41. SYMMETRICAL COMPONENTS FOR A SYMMETRICAL NETWORK

Consider the special case in which the network in Fig. 4 is perfectly symmetrical, i.e., when

$$\left.\begin{aligned} Z_{ab} = Z_{bc} = Z_{ac} \\ Z_{aa} = Z_{bb} = Z_{cc} \end{aligned}\right\} \tag{28}$$

In this case the symmetrical components of the impedances have the values

$$\left.\begin{aligned} Z_{aa0} &= Z_{aa} \\ Z_{aa1} &= 0 \\ Z_{aa2} &= 0 \\ Z_{bc0} &= Z_{bc} \\ Z_{bc1} &= 0 \\ Z_{bc2} &= 0 \end{aligned}\right\} \tag{29}$$

and therefore eqs. (27) reduce to the simple form

$$\left.\begin{aligned} (Z_{aa} - 2Z_{bc})\, I_{a0} &= V_{a0} \\ (Z_{aa} + \ \ Z_{bc})\, I_{a1} &= V_{a1} \\ (Z_{aa} + \ \ Z_{bc})\, I_{a2} &= V_{a2} \end{aligned}\right\} \tag{30}$$

Note that in this case positive sequence currents are due to positive sequence voltages only, negative sequence currents are due to negative sequence voltages only, and zero sequence currents are due to zero sequence voltages only. Hence independent networks can be set up for the three sequences; these are called *sequence networks*. The positive and negative sequence networks are identical,* whereas the zero sequence network is different from these.

Eqs. (30) are equivalent to the single-phase method of calculation which is given in Art. 36 and which applies to all three-phase networks which are perfectly balanced. Therefore no real advantage is gained by the use of symmetrical components in the case of a completely symmetrical network. Furthermore, eqs. (27) are no easier to solve than eqs. (21) from which they were deduced, and therefore the work done in transforming to symmetrical components in a completely unbalanced network is a waste of time.

If the network to be solved has a portion which is unsymmetrical and a portion which is symmetrical, as usually happens in power systems, the advantages of the method of symmetrical components are great; this is illustrated in Art. 42.

42. PARTIALLY SYMMETRICAL NETWORK

As an illustration of the application of symmetrical components to a network which is partially balanced and partially unbalanced, consider the circuit of Fig. 5. This network, consisting of a wye-connected generator, transmission line, and delta-connected

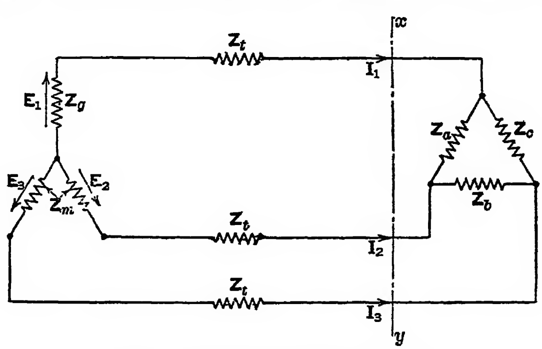

FIG. 5. Partially Symmetrical System

* This is not true of rotating machines.

receiver is symmetrical to the left of section x–y and unsymmetrical to the right. The generator phase voltages will be assumed to have positive phase sequence:

$$\left.\begin{aligned} E_1 &= E_g \angle 0 \\ E_2 &= E_g \angle -120° \\ E_3 &= E_g \angle -240° \end{aligned}\right\} \tag{31}$$

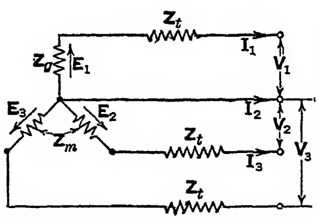

FIG. 6. Symmetrical Generator and Transmission Line

Let the unbalanced load be replaced by three voltages measured from the neutral of the generator. The network to the left of section x–y then appears as shown in Fig. 6 in which V_1, V_2, and V_3 are the voltages replacing the load. Since this network is symmetrical the equations for it may be written down directly by the principle stated in the last article.

$$\left.\begin{aligned} E_{10} - (Z_g + Z_t + 2Z_m)\, I_{10} &= V_{10} \\ E_{11} - (Z_g + Z_t + Z_m)\, I_{11} &= V_{11} \\ E_{12} - (Z_g + Z_t + Z_m)\, I_{12} &= V_{12} \end{aligned}\right\} \tag{32}$$

But V_{10}, I_{10}, E_{10} and E_{12} are all zero so that eq. (32) is simply

$$\left.\begin{aligned} E_{11} - (Z_g + Z_t + Z_m)\, I_{11} &= V_{11} \\ - (Z_g + Z_t + Z_m)\, I_{12} &= V_{12} \end{aligned}\right\} \tag{32a}$$

There remains now the problem of expressing the voltages V_{11} and V_{12} in terms of the symmetrical components of the line currents delivered to the receiver. This is somewhat involved but once solved affords a general formula which can be used in all cases of unbalanced loads. This is done in Art. 43.

43. RECEIVER CURRENTS IN TERMS OF LINE TO GROUND VOLTAGES

In Fig. 7 let P be any arbitrarily chosen point (later to be taken as the neutral of the generator) and let the voltages V_1, V_2, and V_3 be the voltage drops from lines 1, 2, and 3, respectively, to point P. The receiver has been chosen as a delta for convenience; if the actual receiver in a given problem is connected in wye the impedances given here become the impedances of the *equivalent* delta. Note that the point P is perfectly arbitrary and therefore has no relation to the neutral of the wye in a wye-connected receiver. Point P can, for example, be taken at ground potential, whether or not the system is grounded. The currents and voltages are related by the following equations:

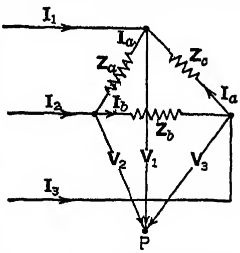

FIG. 7. Unsymmetrical Load

$$\left.\begin{aligned} V_1 - V_2 &= V_a = I_a Z_a \\ V_2 - V_3 &= V_b = I_b Z_b \\ V_3 - V_1 &= V_c = I_c Z_c \end{aligned}\right\} \tag{33}$$

$$\left.\begin{aligned} I_a - I_c &= I_1 \\ I_b - I_a &= I_2 \\ I_c - I_b &= I_3 \end{aligned}\right\} \tag{34}$$

Substitution of (33) in (34) gives

$$\left.\begin{aligned} I_1 &= \frac{V_1 - V_2}{Z_a} - \frac{V_3 - V_1}{Z_c} \\ I_2 &= \frac{V_2 - V_3}{Z_b} - \frac{V_1 - V_2}{Z_a} \\ I_3 &= \frac{V_3 - V_1}{Z_c} - \frac{V_2 - V_3}{Z_b} \end{aligned}\right\} \tag{35}$$

It is more convenient to manipulate the equations if admittances are substituted in place of impedances. Put

$$\left.\begin{aligned} \frac{1}{Z_a} &= A \\ \frac{1}{Z_b} &= B \\ \frac{1}{Z_c} &= C \end{aligned}\right\} \tag{36}$$

in which case eqs. (35) become

$$\left.\begin{aligned} I_1 &= (A + C)V_1 - AV_2 - CV_3 \\ I_2 &= - AV_1 + (A + B)V_2 - BV_3 \\ I_3 &= - CV_1 - BV_2 + (A + C)V_3 \end{aligned}\right\} \tag{37}$$

It is interesting to note that the solutions of eqs. (37) do not exist; i.e., it is impossible to express the V's in terms of the I's. Mathematically this can be proved by observing that the determinant of the coefficients of the V's is zero. Physically this should be expected since the V's are measured to an arbitrary point.

Eqs. (37) are of the same form as eqs. (21) and therefore can be transformed into symmetrical component form by the formulas (27). These symmetrical component equations are

$$\left.\begin{aligned} I_{11} &= (A + B + C)V_{11} + (B + a^2C + aA)V_{12} \\ I_{12} &= (B + aC + a^2A)V_{11} + (A + B + C)V_{12} \end{aligned}\right\} \tag{38}$$

The zero sequence equation and all zero sequence terms drop out. This means physically that there is no relation between the zero sequence components of line current and voltage to ground. Furthermore, the determinant of the coefficients in eqs. (38) is *not* zero; hence a solution exists. This means that although the V's are not determined when the I's are known the *positive* and *negative sequence components* of the V's are determined when the *positive* and *negative* sequence components of the I's are known. In other words, as the point P is moved from place to place the *zero sequence* components of the V's change but the other components remain unchanged.

Solving eqs. (38) for V_{11} and V_{12} and rewriting these in terms of impedances there results

$$\left.\begin{aligned} \frac{Z_a Z_b + Z_b Z_c + Z_a Z_c}{3(Z_a + Z_b + Z_c)} I_{11} - \frac{a^2 Z_a Z_b + aZ_b Z_c + Z_a Z_c}{3(Z_a + Z_b + Z_c)} I_{12} &= V_{11} \\ - \frac{aZ_a Z_b + a^2 Z_b Z_c + Z_a Z_c}{3(Z_a + Z_b + Z_c)} I_{11} + \frac{Z_a Z_b + Z_b Z_c + Z_a Z_c}{3(Z_a + Z_b + Z_c)} I_{12} &= V_{12} \end{aligned}\right\} \tag{39}$$

Hence the general theorem: in any problem involving a three-terminal network the three line currents may be uniquely expressed in terms of the symmetrical components of a group of three-phase voltages having positive and negative sequence components which are unique but of which the zero sequence is arbitrary. This expression is eq. (39).

To complete the problem of the partially symmetrical network of Art. 42 it is necessary to equate the values of V_{11} and V_{12} as given in eqs. (32*a*) and (39). This general scheme yields a convenient means for numerical calculation of unbalanced loading problems and short-circuit currents in three-phase systems.

44. SYMMETRICAL COMPONENT EQUATIONS FOR A THREE-PHASE TRANSDUCER

The general three-phase transformer bank has three pairs of input terminals and three pairs of output terminals. The mesh equations for such a network are

$$\left.\begin{aligned} Z_{aa} I_a + Z_{ab} I_b + Z_{ac} I_c - Z_{au} I_u - Z_{av} I_v - Z_{aw} I_w &= V_a \\ Z_{ab} I_a + Z_{bb} I_b + Z_{bc} I_c - Z_{bu} I_u - Z_{bv} I_v - Z_{bw} I_w &= V_b \\ Z_{ac} I_a + Z_{bc} I_b + Z_{cc} I_c - Z_{cu} I_u - Z_{cv} I_v - Z_{cw} I_w &= V_c \\ - Z_{au} I_a - Z_{bu} I_b - Z_{cu} I_c + Z_{uu} I_u + Z_{uv} I_v + Z_{uw} I_w &= V_u \\ - Z_{av} I_a - Z_{bv} I_b - Z_{cv} I_c + Z_{uv} I_u + Z_{vv} I_v + Z_{vw} I_w &= V_v \\ - Z_{aw} I_a - Z_{bw} I_b - Z_{cw} I_c + Z_{uw} I_u + Z_{vw} I_v + Z_{ww} I_w &= V_w \end{aligned}\right\} \tag{40}$$

This set of equations, when proper values are assigned to the Z's, may be used to express the performance of single-phase transformers in Y–Δ, Δ–Y, etc., or of three-phase transformers. It may also express the performance of synchronous or induction machines. In this case an additional equation (the torque equation) is required. The impedances in eq. (40) are actual self and mutual impedances, not leakage impedances. For numerical accuracy the values of these impedances should be calculated from open- and short-circuit tests in order to eliminate the error which would otherwise arise owing to differences of large quantities. (See Art. 29 of this section.)

Transformation to symmetrical components yields the equations in Table 1.

Table 1

Coefficient of						In equation for

45. SYMMETRICAL COMPONENTS OF INSTANTANEOUS VALUES

The application of the method of symmetrical components is by no means restricted to steady-state calculations in which all the quantities are complex numbers. Symmetrical components of instantaneous values are of great advantage in the solution of transient problems, especially in synchronous machines.

What has been said of vectors is, in general, true of instantaneous values of currents and electromotive forces. The following identities hold:

$$i_a = \frac{i_a + i_b + i_c}{3} + \frac{i_a + ai_b + a^2 i_c}{3} + \frac{i_a + a^2 i_b + ai_c}{3}$$

$$i_b = \frac{i_a + i_b + i_c}{3} + \frac{1}{a}\,\frac{i_a + ai_b + a^2 i_c}{3} + \frac{1}{a^2}\,\frac{i_a + a^2 i_b + ai_c}{3}$$

$$i_c = \frac{i_a + i_b + i_c}{3} + \frac{1}{a^2}\,\frac{i_a + ai_b + a^2 i_c}{3} + \frac{1}{a}\,\frac{i_a + a^2 i_b + ai_c}{3}$$

in which i_a, i_b, and i_c are perfectly arbitrary. Hence the symmetrical components of instantaneous values are defined in the same way as were the symmetrical components of the vector values.

If i_a, i_b, and i_c are sinusoids of the same frequency, the symmetrical components become:

$$i_{a0} = \frac{(I_a e^{j\theta_a} + I_b e^{j\theta_b} + I_c e^{j\theta_c})}{6} e^{j\omega t} + \frac{(I_a e^{-j\theta_a} + I_b e^{-j\theta_b} + I_c e^{-j\theta_c})}{6} e^{-j\omega t}$$

$$i_{a1} = \frac{(I_a e^{j\theta_a} + I_b e^{j\theta_b} e^{j(2\pi/3)} + I_c e^{j\theta_c} e^{j(4\pi/3)})}{6} e^{j\omega t} + \frac{(I_a e^{-j\theta_a} + I_b e^{-j\theta_b} e^{-j(2\pi/3)} + I_c e^{-j\theta_c} e^{-j(4\pi/3)})}{6} e^{-j\omega t}$$

$$i_{a2} = \frac{(I_a e^{j\theta_a} + I_b e^{j\theta_b} e^{j(4\pi/3)} + I_c e^{j\theta_c} e^{j(2\pi/3)})}{6} e^{j\omega t} + \frac{(I_a e^{-j\theta_a} + I_b e^{-j\theta_b} e^{-j(4\pi/3)} + I_c e^{-j\theta_c} e^{-j(2\pi/3)})}{6} e^{-j\omega t}$$

Note that, in the special case in which the currents i_a, i_b, and i_c form a balanced positive sequence group,

$$i_{a0} = 0$$

$$i_{a1} = \frac{I_a}{2} e^{j\omega t}$$

$$i_{a2} = \frac{I_a}{2} e^{-j\omega t}$$

If i_a, i_b, and i_c are not sinusoids but are harmonic quantities having the same fundamental frequency the result is quite complicated. In such cases, however, a type of symmetry such that i_b is obtained from i_a by replacing ωt by $\left(\omega t - \frac{2\pi}{3}\right)$ and i_c from i_a by replacing ωt by $\left(\omega t - \frac{4\pi}{3}\right)$ usually obtains. Further, in power systems, only the odd harmonics appear.

With this type of symmetry the symmetrical components are

$$i_{a0} = \frac{I_a}{2} (e^{j\theta_3} e^{j3\omega t} + e^{j\theta_9} e^{j9\omega t} + \ldots) + \frac{I_a}{2} (e^{-j\theta_3} e^{-j3\omega t} + e^{-j\theta_9} e^{-j9\omega t} + \ldots)$$

$$i_{a1} = \frac{I_a}{2} (e^{j\omega t} + e^{j\theta_7} e^{j7\omega t} + e^{j\theta_{13}} e^{j13\omega t} + \ldots) + \frac{I_a}{2} (e^{-j\omega t} + e^{-j\theta_7} e^{-j7\omega t} + \ldots)$$

$$i_{a2} = \frac{I_a}{2} (e^{j\theta_5} e^{j5\omega t} + e^{j\theta_{11}} e^{j11\omega t} + \ldots) + \frac{I_a}{2} (e^{-j\theta_5} e^{-j5\omega t} + e^{-j\theta_{11}} e^{-j11\omega t} + \ldots)$$

It is also possible to generalize the concept of symmetrical components of impedances so that instead of being restricted to complex numbers they may be differential operators and may if required contain explicit functions of time. The application of this method to eq. (40) affords a method of calculating transients in machines.

ELECTRICAL MACHINES

The calculation of the performance of any electrical machine involves the solution of the electric circuit equations for a group of circuits, some of which move with respect to the others. There are in general two groups of circuits, one group fixed in space (usually called the stator winding) and one group in motion (usually called the rotor winding). Since the self and mutual inductances involved are in general functions of the various currents and of time, many simplifying assumptions are ordinarily made and certain special methods of calculation must be used. Only fundamental considerations are treated in this chapter; for design and performance of machines refer to the particular type of machine of interest.

46. MAGNETOMOTIVE FORCES OF WINDINGS

When a current flows through a constant self- or mutual inductance the voltage produced can easily be calculated by multiplying $\frac{di}{dt}$ by the inductance in question. When the inductance is not constant it is often more convenient to make this calculation in two parts, namely, to calculate first the magnetomotive forces produced by the currents in the various windings and then to find the flux linkages which these magnetomotive forces produce. Thus instead of using the expression

$$e_1 = L_1 \frac{di_1}{dt} + M_{12} \frac{di_2}{dt} + M_{13} \frac{di_3}{dt} + \ldots \tag{1}$$

magnetomotive forces of the type

$$\text{mmf} = 0.4\pi(N_1 i_1 + N_2 i_2 + \ldots) \tag{2}$$

are calculated. The saturation in any particular flux path can then be determined and the flux in that path evaluated by the relation

$$\phi = (\text{mmf})\ (\text{permeance}) \tag{3}$$

The voltage in the winding designated as No. 1, due to this flux, is then

$$e = 10^{-8} \frac{d}{dt} (N_1 \phi) \tag{4}$$

This method of calculating emf, coupled with the methods used normally in electric circuit theory, offers a valuable tool for determining the performance of electrical machines.

In most machines the windings are distributed along the air gap in such a way that the mmf may be assumed to be proportional to the cosine of the angle from the center of a given coil. For example, the magnetomotive force produced at the air gap of a three-phase induction motor or synchronous machine by a direct current I flowing in the stator (armature) windings may be assumed to be given by

$$\left.\begin{aligned} A_a &= NI \cos x \\ A_b &= NI \cos (x - 120°) \\ A_c &= NI \cos (x - 240°) \end{aligned}\right\} \tag{5}$$

in which x is the distance in electrical degrees measured from the center of one of the coil groups of phase a, and N is a factor depending upon the number and arrangement of turns. The resultant magnetomotive force at any point on the stator is the sum of these three magnetomotive forces. Thus with direct current in the windings the resultant mmf A is

$$A = NI[\cos x + \cos (x - 120°) + \cos (x - 240°)] = 0 \tag{6}$$

If the armature windings are excited by means of three alternating currents which form a balanced positive sequence group, the magnetomotive force will be a function of the time as well as of the angle x. Write this mmf as $A_1(x, t)$. The three currents may be written as

$$\left.\begin{aligned} i_{a1} &= \sqrt{2}\, I_{a1} \sin (\omega t - \beta_1) \\ i_{b1} &= \sqrt{2}\, I_{a1} \sin (\omega t - \beta_1 - 120°) \\ i_{c1} &= \sqrt{2}\, I_{a1} \sin (\omega t - \beta_1 - 240°) \end{aligned}\right\} \tag{7}$$

The armature mmf becomes

$$\left.\begin{aligned} A_1 (x, t) &= \sqrt{2}\, NI_{a1} [\sin (\omega t - \beta_1) \cos x + \sin (\omega t - \beta_1 - 120°) \cos (x - 120°) \\ &\quad + \sin (\omega t - \beta_1 - 240°) \cos (x - 240°)] \\ A_1 (x, t) &= \frac{3NI_{a1}}{\sqrt{2}} \sin (\omega t - x - \beta_1) \end{aligned}\right\} \tag{8}$$

47. ROTATING FIELDS

In eq. (8), $A_1 (x, t)$ is the resultant magnetomotive force at a point on the stator at a distance x from the center of one of the coil groups of phase a, expressed as a function of time. If it is desired to find the resultant magnetomotive force at some point on the rotor in terms of the distance from a datum on the rotor structure, say the center of a pole, x may be put equal to the distance from the center of a pole to the point in question plus the distance between the centers of the pole and the coil group. Let the origin of time be taken as the instant at which the center of a coil group of phase a coincides with the center of a pole, so that the distance between the center of the coil group and the center of the pole is simply $\omega_r t$. Let the distance between the center of the pole and the point on the rotor at which the magnetomotive force is desired be y. That is, put

$$x = \omega_r t + y \tag{9}$$

then we have

$$A_1 (y,t) = -\frac{3NI_{a1}}{\sqrt{2}} \sin [y + \beta_1 - (\omega - \omega_r) t] \tag{10}$$

in which $A_1 (y,t)$ is the mmf at a distance $(\omega_r t + y)$ from the center of coil a, or at a distance y from the center of a pole. This quantity is not a function of time when ω and ω_r are equal. Physically this means that the armature currents produce a magnetomotive force which is sinusoidal in space and which rotates at the angular velocity ω. When ω_r is equal to ω there is no relative motion between the armature flux and the field conductors. The result is not limited to the case of three phases; it is readily shown that *any* polyphase winding through which balanced positive sequence currents flow produces

a similar rotating magnetomotive force. The more general theorem is known as the "Theorem of Ferraris."

This principle makes possible certain graphical solutions of synchronous machine problems which are of use when non-linearity of the saturation curve is not neglected. The resultant mmf of the field and armature can be found; and since this resultant is independent of time so far as the field iron is concerned the flux which this mmf produces can be found from a direct-current saturation curve. In this way the problem of *armature reaction* (q.v.) in the synchronous machine is rendered relatively simple. It is important to stress the fact that *armature reaction* is simply a special name applied to a component magnetomotive force involved in the simultaneous solution of two or more mesh equations. Armature reaction is not used in transformer theory because the mmf of the secondary is not constant with time and is not a convenient quantity to use in transformer calculations. Ordinary circuit theory methods are more suitable for that problem.

48. FLUX LINKAGES IN SYNCHRONOUS MACHINES

The space wave form of flux around the periphery of the armature of a synchronous machine is the same as that of the mmf only if the air gap is uniform and if saturation is negligible. Since flux linkages and not mmf determine the electromotive forces in the machines, flux linkage is the quantity which must be evaluated. An approximate method applicable to machines having salient poles was developed by Blondel, on the empirical theory of alternators, *L'Industrie Électrique*, Nov. 10 and 25, 1899. He resolved the resultant mmf acting across the air gap into two sinusoidal components, one having its maximum value at the center of a pole and one having its maximum value at a point midway between the poles.

It is well known that in d-c machines the armature reaction is transverse when the brushes are in the neutral position, and direct when they are shifted 90 electrical degrees from the neutral. It is customary to treat the two reactions separately and to split any armature reaction occurring with the brushes in some intermediate position into two parts. The reaction in a salient pole alternator is fundamentally the same phenomenon. Blondel assumed that the resultant flux could be found by multiplying the magnetomotive force due to the first component by the permeance p_d of the path along the polar axis, multiplying the second component by the permeance p_q of the path along an axis midway between the poles, and adding the results. There is no necessity to restrict this process to balanced positive sequence armature currents, or indeed to restrict it to the armature at all. All magnetomotive forces acting in the air gap can be split into direct and quadrature components, and the flux linkages which these magnetomotive forces produce can then be found. The subsequent analysis follows closely, except for his use of per-unit quantities, the work of Park.*

The components of mmf in the direct and quadrature axes due to the field will be denoted by F_d and F_q. Then the field flux in maxwells per electrical degree is given by

$$F = p_d F_d \cos y + p_q F_q \sin y \tag{11}$$

The mmf in ampere-turns due to the armature was shown in the preceding article to be

$$A(x, t) = N[i_a \cos x + i_b \cos (x - 120°) + i_c \cos (x - 240°)] \tag{12}$$

Putting $x = \omega t + y$ and expanding, there results

$$\begin{aligned} A(x, t) = {} & N \cos y\,[i_a \cos \omega t + i_b \cos (\omega t - 120°) + i_c \cos (\omega t - 240°)] \\ & - N \sin y[i_a \sin \omega t + i_b \sin (\omega t - 120°) + i_c \sin (\omega t - 240°)] \end{aligned}$$

which is seen to be separated into components, one in the direct polar axis and one in the quadrature polar axis. The resultant flux density in maxwells per electrical degree in the air gap is

$$\begin{aligned} b_r = {} & p_d F_d \cos y + p_q F_q \sin y \\ & + 0.4\pi p_d N \cos y[i_a \cos \omega t + i_b \cos (\omega t - 120°) + i_c \cos (\omega t - 240°)] \\ & - 0.4\pi p_q N \sin y[i_a \sin \omega t + i_b \sin (\omega t - 120°) + i_c \sin (\omega t - 240°)] \end{aligned} \tag{13}$$

which may be rewritten in the form

$$\begin{aligned} b_r = {} & p_d F_d \cos (\omega t - x) - p_q F_q \sin (\omega t - x) \\ & + 0.4\pi N \frac{p_q + p_d}{2} [i_a \cos x + i_b \cos (x - 120°) + i_c \cos (x - 240°)] \\ & + 0.4\pi N \frac{p_d - p_q}{2} [i_a \cos (2\omega t - x) + i_b \cos (2\omega t - x - 120°) \\ & + i_c \cos (2\omega t - x - 240°)] \end{aligned} \tag{14}$$

* Park, R. H., Definition of an ideal synchronous machine, *G. E. Rev.*, June, 1928.

The flux linkages in phase a due to the flux b_r are proportionate to the flux density at the axis of coil a. This is the value of eq. (14) when $x = 0$. If N' is the constant of proportionality between flux density and flux linkages, we have

$$\psi_a = N'p_d F_d \cos \omega t - N'p_q F_q \sin \omega t + 0.4\pi NN' \frac{p_d + p_q}{2}\left[i_a - \frac{i_b + i_c}{2}\right]$$
$$+ 0.4\pi NN' \frac{p_d - p_q}{2}[i_a \cos 2\omega t + i_b \cos (2\omega t - 120°) + i_c \cos (2\omega t - 240°)] \quad (15)$$

The value of ψ_a given by eq. (14) represents the total flux linkages in coil a due to flux which crosses the air gap. There will be additional flux linkages due to flux which links coil a only, and due to flux which links coils b and c but which does not cross the air gap. This flux is mostly slot leakage and flux encircling the end connections, and hence has its paths mostly in the air.

The total flux linkages in coil a may be written

$$\psi_a = N'p_d F_d \cos \omega t - N'p_q F_q \sin \omega t + \frac{x_{l\sigma}}{10^{-8}\omega} i_a - \frac{x_m}{10^{-8}\omega}(i_b + i_c)$$
$$+ 0.4\pi NN' \frac{p_d + p_q}{4}\left[i_a - \frac{i_b + i_c}{2}\right]$$
$$+ 0.4\pi NN' \frac{p_d - p_q}{2}[i_a \cos 2\omega t + i_b \cos (2\omega t - 120°) + i_c \cos (2\omega t - 240°)] \quad (16)$$

where $x_{l\sigma}$ = self-leakage reactance of one phase of the armature, and x_m = mutual leakage reactance of any two phases.

It is convenient to write the armature currents in terms of their symmetrical components and to split the armature flux linkages into four parts, the flux linkages due to the field flux and those due to each of the symmetrical components of the armature currents, thus

$$\psi_a = \psi_{af} + \psi_{a0} + \psi_{a1} + \psi_{a2} \quad (17)$$

The flux linkages due to the field are given by

$$\psi_{af} = N'p_d F_d \cos \omega t - N'p_q F_q \sin \omega t \quad (18)$$

The flux linkages due to positive sequence armature currents are

$$\psi_{a1} = \left(\frac{x_{l\sigma}}{\omega 10^{-8}} + \frac{x_m}{\omega 10^{-8}} + 1.2\pi NN' \frac{p_d + p_q}{4}\right)\sqrt{2} I_{a1} \sin (\omega t - \beta_1)$$
$$-1.2\pi NN' \frac{p_d - p_q}{4}\sqrt{2} I_{a1} \sin (\omega t + \beta_1) \quad (19)$$

The flux linkages due to negative sequence armature current are

$$\psi_{a2} = \left(\frac{x_{l\sigma}}{\omega 10^{-8}} + \frac{x_m}{\omega 10^{-8}} + 1.2\pi NN' \frac{p_d + p_q}{4}\right)\sqrt{2} I_{a2} \sin (\omega t - \beta_2)$$
$$+ 1.2\pi NN' \frac{p_d - p_q}{4}\sqrt{2} I_{a1} \sin (3\omega t - \beta_2) \quad (20)$$

The flux linkages due to zero sequence armature currents are

$$\psi_{a0} = \left(\frac{x_{l\sigma}}{\omega 10^{-8}} - \frac{2x_m}{\omega 10^{-8}}\right)\sqrt{2} I_{a0} \sin (\omega t - \beta_0) \quad (21)$$

49. NOMINAL EMF AND ARMATURE REACTANCES

The electromotive forces due to the various flux linkages are easily found. The open-circuit or nominal electromotive force is

$$e_a = - 10^{-8}\frac{d}{dt}\psi_{af} \quad (22)$$

The net induced emf in phase a of the armature is equal to the derivative with respect to time of ψ_a hence the total armature inductive drop is equal to $\frac{d}{dt}(\psi_a - \psi_{af})$. The total inductive drop per unit armature current is the armature reactance. It is apparent that the character of the armature reactance will depend upon whether or not there are salient poles and whether or not the armature currents are balanced. It is customary to ascribe several different " reactances " to a synchronous machine armature, each reactance suitable for a particular type of computation.

Consider a machine having non-salient poles and having equal receiver impedances

connected to the three phases. If there are no salient poles the permeance is the same along any radius and hence

$$p_d = p_q$$

If the receiver impedances are equal the currents form a positive sequence group, hence

$$I_{a0} = I_{a2} = 0$$

It follows, therefore, that the total armature inductive drop is

$$-\left[x_{l\sigma} + x_m + {}^3/_2\,(4\pi\omega NN'p_d\,10^{-9})\right]\sqrt{2}I_{a1}\cos(\omega t - \beta_1) \tag{23}$$

The quantity in the square bracket in eq. (23) is called the *synchronous reactance* of the machine. The synchronous reactance is the effective leakage reactance of the armature plus the combined reactive effect, on one phase of the armature, of all the armature flux which traverses the polar path. The first part is usually called *armature* reactance, and the second part is usually called *armature reaction.* Denote the synchronous reaction by X_s, then

$$X_s = x_{l\sigma} + x_m + {}^3/_2\,\omega(4\pi NN'\,p_d\,10^{-9}) \tag{24}$$

The *synchronous impedance* of the machine is an impedance having a reactive part X_s and a resistive part equal to the armature effective resistance,

$$Z_s = r_a + jX_s \tag{25}$$

The vector equation for the terminal voltage is

$$E_a - Z_s I_a = V_a \tag{26}$$

The synchronous reactance given by eq. (24) is the value of reactance for a salient pole machine when the power factor is such that the armature current is in quadrature with the nominal emf. It does not depend on the permeance of the quadrature path and hence is called the *direct axis synchronous reactance*, and is usually denoted by X_d.

The *quadrature axis synchronous reactance*, denoted by X_q, is defined by the equation

$$X_q = x_{l\sigma} + x_m + {}^3/_2\,\omega(4\pi NN'\,p_q\,10^{-9}) \tag{27}$$

and may readily be seen to be the value of the synchronous reactance for a salient pole machine when the armature current is in phase with the nominal electromotive force.

The reactance to armature currents having zero sequence is often called the *zero sequence reactance* and is denoted by x_0. From eq. (21) this reactance is

$$X_0 = x_{l\sigma} - 2x_m \tag{28}$$

TRANSMISSION LINES

Transmission lines and cables, in contrast to electric circuits such as transformers and machines, have parameters which are *distributed.* The *lumped-parameter* electric circuit theory outlined above cannot be used for transmission line calculations except in special cases in which the lines are electrically short. (The *electrical length* of a line is defined in Art. 55.) A *smooth* line has series resistance, series inductance, shunt conductance or leakance, and shunt capacitance, uniformly distributed along the line. The series constants are usually termed the conductor impedance; the shunt constants are usually called the dielectric admittance.

50. TRANSMISSION LINE EQUATIONS

Consider a transmission line consisting of two parallel wires and having constants *per unit length* given by

Resistance $= r$ ohms
Inductance $= L$ ohms
Leakance $= g$ mhos
Capacitance $= C$ farads

Let x be the distance measured from the receiving end of the line. Consider the change

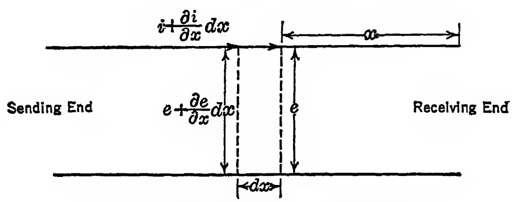

Fig. 1. Section of a Transmission Line

in voltage and current in a differential element dx, Fig. 1. The impedance drop across dx is $\left(rdxi + Ldx\frac{\partial i}{\partial t}\right)$, and the current through the admittance is $\left(gdxe + Cdx\frac{\partial e}{\partial t}\right)$; hence the two equations

$$ri + L\frac{\partial i}{\partial t} = \frac{\partial e}{\partial x} \tag{1}$$

$$ge + C\frac{\partial e}{\partial t} = \frac{\partial i}{\partial x} \tag{2}$$

give the current and voltage at any point on the line at any instant. These partial differential equations are perfectly general and therefore are applicable to both steady-state and transient calculations. Although these equations were established for two parallel wires they may be used for polyphase as well as single-phase calculations. In the polyphase case the series constants are taken per unit length of *wire* instead of per unit length of *line*, and the shunt constants are taken per unit length of wire to neutral. The current is then *per wire* and the voltage is *wire to neutral.*

51. STEADY-STATE CURRENT AND VOLTAGE DISTRIBUTION

If the voltages impressed at the ends of the line have the angular velocity ω, then in the steady state eqs. (1) and (2) become

$$(r + j\omega L)I = \frac{dE}{dx} \tag{3}$$

$$(g + j\omega C)E = \frac{dI}{dx} \tag{4}$$

in which E and I are the vector voltage and vector current at a distance x from the receiver. A more symmetrical form may be obtained by differentiating eqs. (3) and (4) with respect to x and solving for E and for I separately:

$$\frac{d^2E}{dx^2} = (r + j\omega L)(g + j\omega C)E \tag{5}$$

$$\frac{d^2I}{dx^2} = (r + j\omega L)(g + j\omega C)I \tag{6}$$

The solutions of these equations may be written in either of two alternative forms:*

$$E = Me^{\gamma x} + Ne^{-\gamma x} \tag{7}$$

$$I = M'e^{\gamma x} + N'e^{-\gamma x} \tag{7a}$$

* In the following γ is a complex number; due to printing limitations it appears in light face type when in an exponent.

or

$$E = M_1 \cosh \gamma x + N_1 \sinh \gamma x \tag{8}$$

$$I = M'_1 \cosh \gamma x + N'_1 \sinh \gamma x \tag{8a}$$

where

$$\gamma = \sqrt{(r + j\omega L)(g + j\omega C)}$$

The constants M and N in eqs. (7) and (8) are determined by the terminal currents and voltages. Let E_r and I_r be the voltage and current at the receiver and let E_s and I_s be the voltage and current at the source. The E's are both voltage rises; the I's are currents *into* the line from the source and *out* of the line to the receiver. Only the form eqs. (8) and (8*a*) will be given; these are usually most convenient for calculation.

$$E = E_r \cosh \gamma x + Z_c I_r \sinh \gamma x \tag{9}$$

$$I = I_r \cosh \gamma x + \frac{E_r}{Z_c} \sinh \gamma x \tag{9a}$$

$$E = E_s \cosh \gamma y - Z_c I_s \sinh \gamma y \tag{10}$$

$$I = I_s \cosh \gamma y - \frac{E_s}{Z_c} \sinh \gamma y \tag{10a}$$

in which Z_c is defined by

$$Z_c = \sqrt{\frac{r + j\omega L}{g + j\omega C}} \tag{11}$$

and in which y is defined by

$$y = (\text{length of line}) - x \tag{12}$$

Thus the current and voltage at any point in the line may be expressed in terms of the conditions at and distance from the sending end or receiving end, whichever is the more convenient.

52. GENERAL CIRCUIT CONSTANTS

If in eqs. (9) and (9*a*) x is put equal to the length of the line l, the current I and voltage E become those of the source, hence

$$E_s = E_r \cosh \gamma l + I_r Z_c \sinh \gamma l \tag{13}$$

$$I_s = E_r \frac{1}{Z_c} \sinh \gamma l + I \;\cosh \gamma l \tag{14}$$

Comparing these with eqs. (32) and (33) of Linear Circuits, p. 3–15, the general circuit constants are

$$\left.\begin{aligned} A &= \cosh \gamma l \\ B &= Z_c \sinh \gamma l \\ C &= \frac{1}{Z_c} \sinh \gamma l \\ D &= \cosh \gamma l \end{aligned}\right\} \tag{15}$$

By means of these constants the transmission line can be treated in the same way as any other impedance link in a given transmission system. The usual laws for combination in series and in parallel can, of course, be used. See Art. 19. When lines of different characteristics are connected together, as for example an aerial line and an underground cable, the general circuit constants may be calculated separately and then combined.

53. PROPAGATION CONSTANT, CHARACTERISTIC IMPEDANCE

Although less useful in practical calculations the exponential form of solution of the transmission line equations is more valuable in the development of theory. Consider eq. (7).

$$E = Me^{\gamma x} + Ne^{-\gamma x} \tag{7}$$

Both M and N must have the dimensions of voltage; M is often called the *incident* voltage and N the *reflected* voltage. The incident voltage increases in magnitude as we go farther and farther away from the receiver, and the reflected voltage decreases as we go farther and farther away from the receiver. Viewed from the source the incident voltage is *attenuated* as it progresses along the line toward the receiver and the reflected wave builds up, i.e., is attenuated from the receiver. Let γ be written in the form

$$\gamma = \alpha + j\beta \tag{16}$$

then the factor $e^{\gamma x}$ may be written

$$e^{\gamma x} = e^{\alpha x} \angle \beta x \tag{17}$$

Hence α is the quantity which causes a change in magnitude of the incident or reflected voltage, and β is the quantity which causes a phase shift in the voltage.

For this reason α is called the *attenuation* constant, β the *phase shift* constant, and γ the *propagation* constant of the line.

In the special case in which the receiver impedance is equal to the impedance Z_c defined by eq. (11),

$$I_r Z_c = E_r$$

and eqs. (9) and (9a) become

$$E = E_r(\cosh \gamma x + \sinh \gamma x) = E_r e^{\gamma x} \tag{18}$$

$$I = I_r(\cosh \gamma x + \sinh \gamma x) = I_r e^{\gamma x} \tag{19}$$

If such is the case the reflected voltage and current disappear and the line is said to be *smoothly terminated.*

The impedance at any point in the line, from eqs. (9) and (9a), is

$$Z = \frac{E}{I} = \frac{(E_r + I_r Z_c)e^{\gamma x} + (E_r - I_r Z_c)e^{-\gamma x}}{(E_r + I_r Z_c)e^{\gamma x} - (E_r - I_r Z_c)e^{-\gamma x}} Z_c \tag{20}$$

For an infinite line the impedance is

$$Z_\infty = \lim_{x \to \infty} Z = Z_c \tag{21}$$

The impedance Z_c is therefore the impedance at any point of an infinite line; it is also the impedance at any point of a smoothly terminated line. This impedance is called the *characteristic* or *surge impedance* of the line.

54. SHORT- AND OPEN-CIRCUIT IMPEDANCES

If the receiving end of the line is short-circuited E_r is zero and the input impedance becomes

$$Z_{ss} = Z_c \tanh \gamma l \tag{22}$$

If the receiving end is open, I_r is zero and the input impedance becomes

$$Z_{s0} = Z_c \coth \gamma l \tag{23}$$

From these relations the following simple expression for the characteristic impedance is derived

$$Z_c = \sqrt{Z_{ss} Z_{s0}} \tag{24}$$

We have also

$$\gamma = \tanh^{-1} \frac{Z_{ss}}{Z_c} = \coth^{-1} \frac{Z_{s0}}{Z_c} \tag{24a}$$

55. ELECTRICAL LENGTH

One *wavelength* is a length of line such that when smoothly terminated the phase shift in current or voltage is 360 deg. The same phase shift will, of course, occur in the same length of an infinite line having the same constants. Thus in general the wavelength λ of a line is

$$\lambda = \frac{2\pi}{\beta} \tag{25}$$

A line whose physical length is short in comparison with one-quarter wavelength is said to be electrically short. If the length of line is an appreciable fraction of one-quarter wave it is said to be electrically long. Most power transmission lines are electrically short.

56. TRANSIENTS IN TRANSMISSION LINES

The calculation of transmission line transients is extremely specialized and will be considered in outline only.

The steady-state transfer impedance from the sending end of the line to any other point at a distance y from the sending end may be shown to be

$$Z_y = Z_c \left[\frac{(Z_r + Z_c)e^{\gamma l} + (Z_r - Z_c)e^{-\gamma l}}{(Z_r + Z_c)e^{\gamma(l-y)} - (Z_r - Z_c)e^{-\gamma(l-y)}} \right] \tag{26}$$

In "Electric Circuits, Transient State," (Handbook of Engineering Fundamentals Eshbach, John Wiley & Sons), the expression

$$\frac{1}{\beta Z(\beta)} = \int_0^{\infty} e^{-\beta t}\, h(t) dt \tag{27}$$

is given for the *indicial admittance* $h(t)$. In this expression the quantity $Z(\beta)$ is the transfer impedance as a function of the parameter β.

Hence for a transmission line the indicial admittance is given by the Laplace integral

$$\int_0^{\infty} e^{-\beta t}\, h_y(t) dt = \frac{1}{\beta Z_c(\beta)}\left[\frac{1 + U(\beta)}{e^{-y\gamma(\beta)} - U(\beta) e^{y\gamma(\beta)}}\right] \tag{28}$$

in which

$h_y(t)$ = transfer indicial admittance from the sending end to a point y from the sending end.

$Z_c(\beta) = \sqrt{\frac{r + \beta L}{g + \beta C}}$.

$\gamma(\beta) = \sqrt{(r + \beta L)(g + \beta C)}$.

$U(\beta) = \left[\frac{Z_r(\beta) - Z_c(\beta)}{Z_r(\beta) + Z_c(\beta)}\right] e^{-2l\gamma(\beta)}$.

$Z_r(\beta)$ = impedance of the receiver impedance when the angular frequency $j\omega$ is replaced by β.

For methods of solving eq. (28) refer to Carson, J. R., Electric Circuit Theory and Operational Calculus, McGraw-Hill Book Co.; and Campbell and Foster, Fourier integrals for practical applications, *B.S.T.J.*, September, 1931.

Having determined the indicial admittance the current due to any applied emf is

$$i_y(t) = \frac{d}{dt}\int_0^{t} h_y(t - \lambda) E(\lambda) d\lambda \tag{29}$$

in which

$i_y(t)$ = current at a distance y from the sending end.
$E(t)$ = sending-end voltage.
λ = a variable of integration.

STABILITY OF POWER SYSTEMS

The term stability as applied to a power system has a comparatively loose meaning. In general it may be defined as the ability of the system to operate intact without loss of synchronism of the various component generating units. This concept of stability is essentially different from that of dynamic stability defined in the chapter entitled "Transients," Handbook of Engineering Fundamentals, Eshbach, John Wiley & Sons.

A brief non-mathematical treatment of the subject is given in Sect. 14, Art. 18.

57. DEFINITIONS OF STABILITY TERMS

The following definitions were reported by the Committee on Definitions of the A.I.E.E. in January, 1932, and will be used in this chapter.

Stability, when used with reference to a power system, is that quality of the system or part of the system which enables it to develop restoring forces between the elements equal to or greater than the disturbing forces so as to restore a state of equilibrium between the elements.

Steady-state Stability * exists in a power system if it operates with stability when there is no aperiodic disturbance on the system.

Transient Stability * exists in a power system if after an aperiodic disturbance has taken place the system regains steady-state stability.

A Stability Limit is the maximum power transfer through some particular point in the system when the entire system or the part of the system to which the stability limit refers is operating with stability.

The Steady-state Stability Limit is the maximum power transfer through some particular point in the system when the entire system or the part of the system to which the stability limit refers is operating with steady-state stability.

The Transient Stability Limit is the maximum power transfer through some particular point in the system when the entire system or the part of the system to which the stability limit refers is operating with transient stability.

A Stability Factor is the ratio of a stability limit to the nominal power transfer at the point of the system to which the stability limit is referred.

The Steady-state Stability Factor of a system or part of a system is the ratio of the steady-state stability limit to the nominal power transfer at the point of the system to which the stability limit is referred.

The Transient Stability Factor of a system or part of a system is the ratio of the transient stability limit to the nominal power transfer at the point of the system to which the stability limit is referred.

Infinite Bus is frequently used in discussions of power system stability. An infinite bus is a point at which the voltage is constant in modulus, phase, and frequency, independent of the active and reactive power which flows in or out at the point. This condition is approached when the generating capacity connected to the point is extremely large in comparison to the power flow under consideration. The limiting condition of zero synchronous machine impedance and infinite capacity may be thought of as an infinite bus.

58. GENERAL STABILITY PROBLEM

Because of the almost unlimited complexity of electrical power systems and their interconnections, complete stability studies, taking into consideration separately each of the synchronous machines connected to the system and each impedance link involved in their interconnection, would entail so much calculation as to be impracticable. On the other hand, many simplifying assumptions can be made which serve to reduce the labor greatly but still yield results sufficiently accurate for all practical purposes. The simplifications of networks, solution by calculating boards (either of the alternating- or direct-current type), and the construction of mechanical models have all played important parts in the study of system stability.

For the purpose of analysis it is customary to break the general problem down into component problems each simple enough to allow calculation and each representing an important practical case. These component problems are:

1. *Line between infinite buses.* The steady-state power limit of a given transmission link is one limiting factor in system stability. It is apparent that a transmission link operating at its power limit offers no possibility of additional power transfer between the synchronous apparata at its terminals; hence the system is inherently unstable. This represents the practical case of two metropolitan areas, each having a large installed capacity, connected by a tie line. This case is given in Art. 59.

2. *One machine on an infinite bus.* The steady-state and transient stability limits of one machine connected by means of a transducer to an infinite bus present an extremely important practical problem. This arises when a distant hydroelectric station of relatively small capacity is connected by a transmission line to a metropolitan system of large capacity. It may be assumed in this case that all the water-wheel generators act as a unit at the hydro-station bus and that all the turbo-generators combine to produce an effective infinite bus at the receiving end of the line. This case is given in Art. 62.

3. *Two-machine problem.* If the turbo-generator capacity in the above case is not large in comparison with the hydro station, or if two machines or groups of machines of nearly equal capacity are connected together, it is not permissible to assume one to act as a fixed reference; hence the infinite bus concept cannot be used. This case is given in Art. 63.

4. *Many-machine problem.* If a more rigorous analysis is desired than can be obtained by reduction of the network to one of the above simple cases, it is usually necessary to

* If automatic devices are used to aid stability their use should be indicated by the following phrases: steady-state stability with automatic devices; transient stability with automatic devices.

resort to some mechanical or quasi-experimental method of calculation. References applying to such means of calculation are given in the bibliography.

59. LINE BETWEEN INFINITE BUSES

Let the transmission link (transmission line, terminating transformers, etc.) between two points which may be considered as infinite buses be represented by its general circuit constants.

$$E_s = AE_r + BI_r \tag{1}$$

$$I_s = CE_r + DI_r \tag{2}$$

in which E_s and E_r are the voltages maintained by the infinite buses, I_s is the current flowing into the line from the source, and I_r is the current flowing out of the line at the receiver (Fig. 1).

FIG. 1. Single Line Diagram of a General Circuit

If the constants A, B, C, and D are written in the form

$$A = A\ \angle\alpha$$
$$B = B\ \angle\beta$$
$$C = C\ \angle\gamma$$
$$D = D\ \angle\delta$$

and if the angle by which E_r lags E_s is denoted by θ then the input to the line at the sending end is

$$P_s = E_s^2 \frac{D}{B} \cos(\beta - \delta) - \frac{E_r E_s}{B} \cos(\beta + \theta) \tag{3}$$

$$P_r = -E_r^2 \frac{A}{B} \cos(\beta - \alpha) + \frac{E_r E_s}{B} \cos(\beta - \theta) \tag{4}$$

The maximum value which the power input P_s can have, when the modulus values E_r and E_s are constant, occurs when the phase angle between E_r and E_s is given by

$$\frac{dP_s}{d\theta} = 0 \tag{5}$$

or when

$$\sin(\beta + \theta) = 0 \tag{5a}$$

The value $\theta = -\beta$ corresponds to minimum power, and the value

$$\theta = 180° - \beta \tag{5b}$$

gives the condition for the power to be a maximum.

This maximum value is

$$P_{s(\max)} = E_s^2 \frac{D}{B} \cos(\beta - \delta) + \frac{E_r E_s}{B} \tag{5c}$$

The maximum value which the power output P_r can have when the modulus values E_r and E_s are constant occurs when θ satisfies the equation

$$\frac{dP_r}{d\theta} = 0 \tag{6}$$

or when

$$\sin(\beta - \theta) = 0 \tag{6a}$$

The value $\theta = \beta$ corresponds to the smallest absolute value of the negative power, and the value

$$\theta = 180° + \beta \tag{6b}$$

gives the condition for the negative power to have its greatest absolute value. This maximum value is

$$P_{r(\max)} = -\left[E_r^2 \frac{A}{B} \cos(\beta - \alpha) + \frac{E_r E_s}{B}\right] \tag{6c}$$

When the transmission link is operating at the condition given by either eq. (5c) or (6c) no synchronizing power can be transferred as a result of a phase shift of either of the terminal voltages; hence the system is unstable.

60. TORQUE-ANGLE CHARACTERISTICS

The following idealizing assumptions are made:

(a) That all synchronous machines can be represented by equivalent cylindrical rotor machines.

(b) That all loads can be represented by equivalent constant impedance shunts or equivalent synchronous machines.

(c) That damping can be neglected.

(d) That the generator emf's remain constant in modulus value.

Eqs. (3) and (4) represent the power input and output of a given transmission link as a function of the angle between its terminal electromotive forces. Suppose that a synchronous machine is connected through a transducer to an infinite bus. Take E_r as the voltage at the infinite bus. Then the general circuit constants may be made to include the synchronous machine impedance, and E_s may be taken as the machine emf. If the calculations are for steady state the synchronous impedance and nominal emf of the machine should be used. If the calculations are for transients the transient reactance and emf due to air-gap flux should be used. (This neglects the effect of subtransient reactance, which is permissible in most stability calculations.) When these substitutions have been made, eq. (3) gives the electrical power output of the generator as a function of its rotor position with respect to the reference established by the infinite bus. Such a curve is called a *power-angle characteristic*. Since the speed of the machine is constant under steady-state conditions and may be assumed to be constant with good accuracy so far as torque calculations are concerned, this characteristic when expressed in per-unit quantities may also be regarded as a *torque-angle characteristic*.

If, instead of a machine connected to an infinite bus, two machines of finite capacity are connected together through a transducer, the powers are given by eqs. (3) and (4) providing the E's are regarded as the generator electromotive forces and the general circuit constants include the impedance of both synchronous machines.

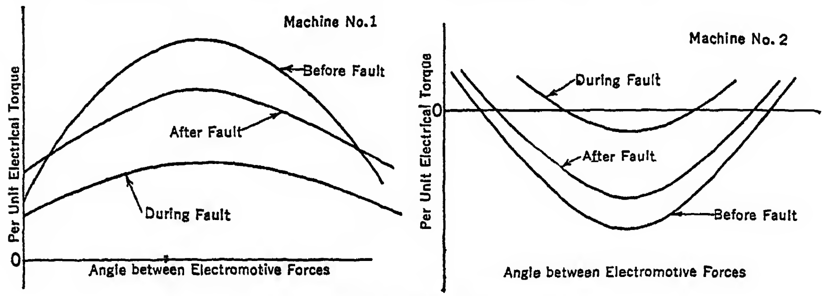

FIG. 2. Torque-angle Characteristics

Since in these applications of eqs. (3) and (4) the terms "source" and "receiver" lose their significance (both will frequently be sources), it will be convenient to rewrite the equations in a slightly different and more symmetrical form:

$$P_1 = \frac{E_1^2}{Z_{11}} \sin \alpha_{11} + \frac{E_1 E_2}{Z_{12}} \sin (\theta - \alpha_{12}) \tag{7}$$

$$P_2 = \frac{E_2^2}{Z_{22}} \sin \alpha_{22} + \frac{E_1 E_2}{Z_{12}} \sin (\theta + \alpha_{12}) \tag{8}$$

In these equations E_1 = modulus value of electromotive force of machine 1 (nominal emf or voltage-behind-transient-reactance as required).

E_2 = modulus value of electromotive force of machine 2 (nominal emf or voltage-behind-transient-reactance as required).

θ = angle between E_1 and E_2.

$Z_{11} = Z_{11}\angle\theta_{11}$ = input impedance to the transducer at machine 1.

$Z_{22} = Z_{22}\angle\theta_{22}$ = input impedance to the transducer at machine 2.

$Z_{12} = Z_{12}\angle\theta_{12}$ = transfer impedance of the transducer.

$\alpha_{11} = 90° - \theta_{11}$.

$\alpha_{22} = 90° - \theta_{22}$.

$\alpha_{12} = 90° - \theta_{12}$.

P_1 = power *output* of machine 1.

P_2 = power *output* of machine 2.

Eqs. (7) and (8) apply to a particular transducer. If a fault occurs, or if a line within the transducer is switched in or out, the input and transfer impedances will change. Representative torque angle characteristics before, during, and after the clearing of a fault are shown in Fig. 2.

61. ROTOR ACCELERATION

Let θ be the angular position of the rotor of a given machine with respect to an arbitrary reference which runs at synchronous speed. Then the acceleration is given by

$$\frac{d^2\theta}{dt^2} = \frac{\pi f \Delta P}{H'} \tag{9}$$

in which f is the frequency in cycles per second, ΔP is the power available to produce acceleration, and H' is the kinetic energy of rotation of the machine and its prime mover. H' in kilowatt-seconds is given by

$$H' = 2.31 \text{ (moment of inertia) (rpm)}^2 \times 10^{-7} \tag{10}$$

Let H be the value of H' per unit *kva*.

$$H = \frac{H'}{\text{base } kva} \text{ seconds} \tag{11}$$

Then in per-unit quantities

$$\frac{d^2\theta}{dt^2} = \pi f \frac{\Delta T}{H} \tag{12}$$

in which ΔT is the net torque available to accelerate the rotor.

If T = per-unit mechanical torque (positive for input to a machine) and T_e = per-unit electrical torque (positive for output from the machine) then the accelerating torque is

$$\Delta T = T - T_e \tag{13}$$

The torque ΔT is in general a function of the angle θ. If eq. (12) is multiplied by $\frac{d\theta}{2dt}$ and integrated with respect to t, the following integral equation results

$$\left(\frac{d\theta}{dt}\right)^2 = 2\pi f \int_{\theta_0}^{\theta} \frac{\Delta T}{H}\, d\theta \tag{14}$$

This gives the rotor velocity as an area under the accelerating-torque versus angle characteristic.

62. ONE MACHINE ON AN INFINITE BUS

Consider a synchronous machine connected to an infinite bus by means of a transducer. Eq. (7) gives the power output of the machine which, if expressed in per-unit quantities, is also the electrical torque; hence

$$T_{e1} = \frac{E_1^2}{Z_{11}} \sin\alpha_{11} + \frac{E_1 E_2}{Z_{12}} \sin(\theta - \alpha_{22}) \tag{15}$$

In this equation, θ is the angle between the machine rotor and the reference established by the infinite bus.

The torque T_{e1} is taken with the positive sign if it acts *against* the direction of rotation, i.e., positive for an output from the machine. For static stability the electrical torque should increase when θ increases and decrease when θ decreases; this gives rise to a counterbalancing torque tending to pull the machine in synchronism when, for any reason, there is an incremental swing of the rotor away from synchronism. It is assumed that all changes occur slowly so that inertial effects are negligible. The condition for stability is

$$\frac{dT_{e1}}{d\theta} > 0$$

which results in the equation

$$\cos(\theta - \alpha_{12}) > 0 \tag{16}$$

or θ must satisfy the inequality

$$\alpha_{12} - \frac{\pi}{2} < \theta < \alpha_{12} + \frac{\pi}{2} \tag{16a}$$

In terms of the angle θ_{12} of the transfer impedance Z_{12} this becomes

$$-\theta_{12} < \theta < \pi - \theta_{12} \tag{17}$$

In order to determine whether or not the machine is operating with transient stability it is necessary to investigate the acceleration equation. Suppose the machine to be operating in equilibrium so that the mechanical torque and electrical torque are equal. This is represented by the operating point O in Fig. 3, at which point θ has the value θ_0. If a fault occurs, changing the torque-angle characteristic from the curve A to the curve B, an excess of mechanical over electrical torque arises which tends to speed up the machine. During the interval of time after the occurrence of a fault and before the clearing of the

fault the machine continues to be accelerated. At the instant of clearing, say at an angle θ', the accelerating torque changes from the value by cb on Fig. 3 to the value given by dc. Note that the sign has changed. During the interval after clearing and before reaching some point such as g, at which the accelerating torque again changes sign, the rotor slows up. If there exists a value of θ such as θ'' at which the velocity of swing is zero the machine will not lose synchronism on the first swing. It will be assumed that, because of damping, if synchronism is not lost on the first swing it will not be lost at all.

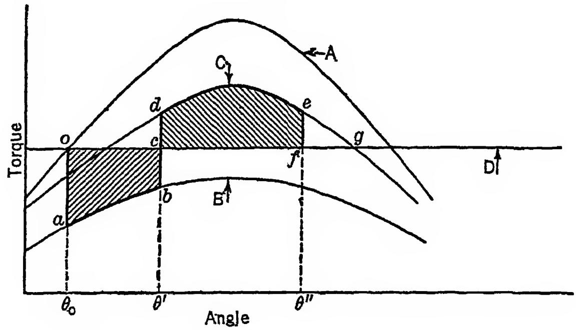

FIG. 3. Torque-angle Characteristics Showing Effect of Switching.

From eq. (14) it is apparent that the condition for the existence of a point of zero velocity is that

$$\int_{\theta_0}^{\theta} \frac{\Delta T}{H} d\theta = 0 \tag{18}$$

or in other words that the area $oabc$ in Fig. 3 be equal to the area $cdef$. This is known as the "equal area" criterion for stability.

After the angle θ', at which clearing of the fault must occur for the system to remain stable, has been determined from a diagram such as Fig. 3, it is necessary to find the time interval within which the relays must operate. The solution of the differential equation (14) can be accomplished by step-by-step processes, or by mechanical means such as a differential analyzer.

63. TWO-MACHINE PROBLEM

If, instead of one machine connected to an infinite bus, two machines of comparable capacities must be considered, a slight modification of the analysis in Art. 62 may be used.

In the study of steady-state stability both ends of the transducer must be considered. Hence the condition for steady-state stability is that both

$$\frac{dT_{e1}}{d\theta} > 0$$

and

$$\frac{dT_{e2}}{d\theta} > 0$$

simultaneously, if the machines are not to lose synchronism with each other. These conditions result in the equations:

$$\cos(\theta - \alpha_{12}) > 0 \tag{19}$$

$$\cos(\theta + \alpha_{12}) > 0 \tag{20}$$

or θ must satisfy the two inequalities

$$\alpha_{12} - \frac{\pi}{2} < \theta < \alpha_{12} + \frac{\pi}{2}$$

$$-\alpha_{12} - \frac{\pi}{2} < \theta < -\alpha_{12} + \frac{\pi}{2}$$

In terms of the angle θ_{12} of the transfer impedance Z_{12} these conditions become

$$-\theta_{12} < \theta < \pi - \theta_{12}$$

$$\theta_{12} - \pi < \theta < \theta_{12}$$

In other words, the angle θ between the two generator electromotive forces must be greater than the greater of the two quantities $-\theta_{12}$ and $(\theta_{12}-\pi)$ and less than the smaller of the two quantities

$$\theta_{12} \quad \text{and} \quad (\pi - \theta_{12})$$

In calculating the conditions for transient stability in the two-machine problem the *relative* motion of the two rotors is of importance. If the system accelerates or decelerates as a whole but does not lose synchronism it is still stable according to the definition given in Art. 57. The two equations.

$$\frac{d^2\,\theta_1}{dt^2} = \pi f \frac{\Delta T_1}{H_1} \tag{22}$$

and

$$\frac{d^2\,\theta_2}{dt^2} = \pi f \frac{\Delta T_2}{H_2} \tag{23}$$

give the accelerations of the two rotors with respect to some arbitrary datum. Put $\delta = \theta_1 - \theta_2$; then δ is the angle of relative swing of the rotors with respect to each other.

$$\frac{d^2\,\delta}{dt^2} = \frac{d^2\,\theta_1}{dt^2} - \frac{d^2\,\theta_2}{dt^2}$$

hence

$$\left(\frac{d\,\delta}{dt}\right)^2 = 2\pi f \int_{\delta_0}^{\delta} \left(\frac{\Delta T_1}{H_1} - \frac{\Delta T_2}{H_2}\right) d\,\delta \tag{24}$$

This expression can be used to calculate the condition for relative synchronous operation between two machines in exactly the same way as eq. (14) was used to calculate the condition for absolute synchronous operation of one machine with respect to a fixed system of reference. The angle δ is the angle between the two generator electromotive forces; therefore the electrical-torque versus angle characteristics are as shown in Fig. 2. The condition for stability is that there must exist a value of δ for which the equation

$$\int_{\delta_0}^{\delta} \left(\frac{\Delta T_1}{H_1} - \frac{\Delta T_2}{H_2}\right) d\,\delta = 0 \tag{25}$$

is satisfied. If a switching angle can be found so as to make eq. (25) true then the differential equation (24) determines the interval of time during which the clearing of a fault must be accomplished.

64. METHODS OF IMPROVING STABILITY *

The following means are available for generally improving the stability of power systems:

1. Reduction of series reactance.
2. Suitable arrangement of buses.
3. Grounding of the neutral.
4. Improvement in generator design.
5. Rapid response excitation.
6. Ultra rapid relays and circuit breakers.
7. Regulation of prime movers.
8. Artificial loading of generators during fault period.
9. Intermediate synchronous condenser stations.
10. Protection against lightning and suppression of arcs.
11. Transmission by means of low frequency or direct current.

REDUCTION OF SERIES REACTANCE. The most evident way of increasing the limits of stability of a system consists in decreasing the value of the reactance of the synchronous machines, for thus the synchronising power which can be exchanged is increased.

The reactance of a transmission line can be reduced by increasing the diameter of the conductor, by using a metal having low conductivity or by using a hollow cable; however, the characteristics of conductors are habitually fixed for economical reasons totally unrelated to stability. Another means of lowering the reactance of a line is to reduce the spacing of the conductors. This again is normally determined by other considerations, such as protection against lightning and against the spread of arcs on one phase to another.

The placing of capacitances in series furnishes another means of diminishing the reactance of transmission systems. However, at the instant at which a disturbance occurs, the current which goes through the condenser greatly increases the voltage drop

* Most of the material in this article was abstracted from R. D. Evans and C. F. Wagner, La stabilité des systèmes de transmission d'énergie électrique, *C.I.E.*, Vol. VI, No. 5.

across it so that it is necessary to short-circuit it to avoid the breakdown. The condenser is therefore suppressed at the moment when there is the greatest need for it.

The reactance of transformers is largely determined by economic considerations; therefore there is little opportunity for improvement in stability in this way.

The most practical procedure for lowering the reactance of transmission lines is to have several lines in parallel or to use circuits with higher voltage. There are the two alternatives; a great number of lines at low voltage in parallel, or a smaller number of circuits at high voltage. An important consideration is that, with a small number of circuits, the break of a line reduces the limit of stability by a relatively larger amount.

ARRANGEMENT OF BUSES. The placing in parallel of the high-tension sides of transmission lines at their termination, or at intermediate points, produces a smaller increase of reactance at the moment of clearing of a fault than when the connection is made on the low-tension side, for in the latter case, not only the transmission line itself but also the corresponding transformers are removed from the circuit. On the other hand, for the duration of the fault, the shock sustained by the system is more violent if the connection is made on the high-tension side than if it is made on the low-tension side. It is impossible to draw any general conclusions as regards the advantage of one or the other of these arrangements, for in each particular case the effect depends on the relations between the different reactances of the system, the type of fault, its duration, and the type of ground used.

The scheme known by the term "synchronization at the load," such as is applied to metropolitan networks, employs another method of paralleling. In this scheme there are no direct connections between the synchronous machines, but only an indirect coupling afforded by the multiple connections in the low-voltage network. With this arrangement, the faults on the secondary network have no serious repercussions on the system and can be eliminated by fusion. A short circuit on one of the generator buses causes the disconnection of that unit, but the other machines, although submitted to a violent shock, become accelerated or slowed down as a group.

Although the "synchronized at the load" system was developed for supplying metropolitan areas with power, the general principle can be applied to long-distance transmission. The modification of the scheme in this case consists in connecting the different lines only on the low-voltage sides at the receiving end.

GROUNDING OF THE NEUTRAL. In America, the current practice is to ground the neutral directly on the high-tension systems and, either indirectly or by means of a resistance, on the intermediate-voltage networks. Petersen earth coils have not been adopted, although they have been tried in two places. The introduction of impedances in the neutral, by limiting the seriousness of the faults, raises the limits of stability. This may come about in either of two ways. If the impedance is a pure reactance the fault current is reduced, and it follows that the synchronizing power is increased. If the impedance is a resistance, it absorbs some energy, loads the generator, and thus decreases the acceleration of the latter. In general, however, the type of ground used is usually determined by considerations other than stability.

IMPROVEMENT IN GENERATOR DESIGN. The best criterion, from the viewpoint of stability, of the functioning of a generator is its transient reactance. This must be as small as possible. This result can usually be obtained by a slight additional cost with respect to that of the normal machine. The short-circuit ratio which is approximately the inverse of the synchronous reactance does not matter from the viewpoint of stability, except in cases of static operation without voltage regulators.

The increase in inertia of the rotor of the generator or of that of the prime mover decreases the acceleration at the instant of a disturbance, and in this way is favorable to stability. The improvement which can be expected from this source will depend on the arrangement and the constants of the system, but it is small in general.

The seriousness of disymmetrical faults on a network depends upon the negative sequence impedance of the machine. Machines without amortisseurs have large negative sequence reactances and from this point of view are more desirable; on the other hand, machines with amortisseurs have large negative sequence resistances. The improvement gained by the use of high-resistance amortisseurs is quite appreciable for prolonged faults, but it is much less for faults whose duration is of the order that can be attained now with ultra-rapid interrupters. Low-resistance amortisseurs are much more effective than those of high resistance in damping out rotor oscillations but are worthless during faults. A double squirrel-cage arrangement in which the exterior cage is highly resistive and the inner cage is of low resistance and high reactance unites these principles.

The increase in size of the generating units, causing a greater concentration of power on a single bus, has increased the work of the circuit breakers and the extent of the zone affected by a given fault. This effect has been greatly reduced with the use of alternators

with two armature windings in which the two circuits of the stator are linked only by their mutual inductance. Each armature is connected to a separate bus; if a fault occurs on one of them, the disturbance limits itself to this bus. The tendency of the rotor to accelerate will thus be very much decreased. Generators of this type lend themselves well to be incorporated as units in " synchronized at the load " systems.

RAPID RESPONSE EXCITATION. The regulating of the excitation of synchronous machines furnished a practical means of raising the limits of both dynamic and static stability. Short circuits increase the demagnetizing effect of the armature, and this effect can be counterbalanced by an increase of excitation at a suitable rate. A system of excitation with sufficiently rapid response for this purpose requires that the regulator have rapid response, that the exciter itself be capable of responding rapidly, and that the exciter have a large ratio of maximum voltage to normal voltage.

The field circuits of exciters for this purpose must have low time constants; this is accomplished by placing them in series with exterior resistors, laminating the stator, etc. Often a pilot exciter, which in turn supplies the main exciter, is used.

The means of rapid excitation are effective not only when there is a question of counterbalancing the demagnetizing action of short-circuit currents, but also in supplying an important lack of excitation arising somewhere in the network; for example, following the cutting of the excitation of a unit, or the sudden disconnection of a machine which is very much overexcited. This peculiarity of rapid response excitation permits anticipation of serious disturbances against which ultra-rapid circuit breakers and similar devices are ineffective.

ULTRA-RAPID RELAYS AND CIRCUIT BREAKERS. As shown in Arts. 62 and 63 the duration of a fault up to its clearing is of paramount importance in determining whether or not the system remains stable. This is illustrated in Fig. 4. These curves show the limits of dynamic stability of a standard system whose constants are indicated in the figure as a function of the duration of the fault. The dotted curves give the transmissible load for permanent short circuits of the indicated types. Rapid response excitation is assumed to exist.

The importance of ultra-rapid relays and circuit breakers cannot be overstressed since their use is essential to the satisfactory operation of practically all large transmission systems. They constitute the most practical means yet developed to improve stability.

It has been suggested that the cutting of the defective phase only may be advantageous in cases of line to ground faults. In this way the remaining phases serve to maintain load on the generator so that the acceleration during the fault period is reduced.

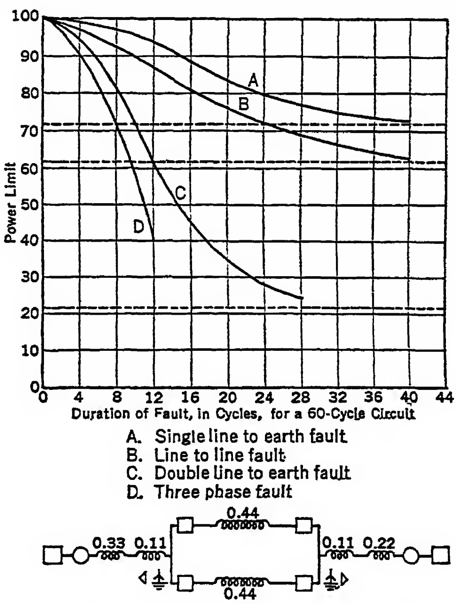

FIG. 4. Effect of the Duration of Fault on the Power Limit for Various Types of Fault. (This figure is reprinted from Evans, R. D., and Wagner, C. F., La Stabilité des Systèmes de Transmission d' Énergie Électrique, Vol. VI, Comptes Rendué du Congrès International d' Electricité.

The other means suggested for the improvement of stability are for the most part in the development stage and will not be discussed in detail.

RESISTORS, REACTORS, MAGNETS

By A. Dexter Hinckley

RESISTORS, RHEOSTATS

A resistor is a device, the primary purpose of which is to introduce resistance into an electric circuit. It consists essentially of an electrical conductor, usually of relatively high resistivity, formed in such a manner that a relatively high resistance is enclosed in a relatively small volume. A rheostat is an adjustable resistor so constructed that its resistance may be adjusted without opening the circuit in which it is connected.

Generally, resistors and rheostats find their applications in circuits for current and voltage adjustment. For applications in the field of power engineering such duties are performed on direct or low-frequency currents. Since the effects of residual inductance and capacitance in a resistor are generally negligible for continuous currents or currents of low frequency, the resistor will be considered, in this chapter, purely as a device for energy dissipation.

1. GENERAL CONSIDERATIONS

ENERGY DISSIPATION. As a circuit element, the resistor generally has current flowing through it, either continuously or intermittently. The electrical energy dissipated in the device may be measured from the power,

$$P = I^2r$$

where P is the power in watts, I the effective current in amperes, and r the resistance in ohms for the conditions under which the resistor is operating. If the current remains constant for t seconds the energy dissipated in the resistor is

$$\text{Energy} = I^2 rt \text{ joules (or watt-seconds)}$$

This mathematical statement of Joule's law indicates that the total energy dissipated in the resistor goes into the form of heat.

TEMPERATURE OF RESISTOR. The various materials making up resistors are variously affected by the resultant temperature change. Conductor resistivities vary, conductor and supporting insulators change their dimensions, and qualities of physical and electrical strength may be seriously affected. Temperatures may be reached which constitute a definite fire hazard to nearby materials. All these factors must be considered in the design and construction of the resistor, and each bears different weight in the different resistor forms. In order to safeguard against the various possibilities noted above, certain standards of temperature rise have been designated. The American Standard states that " The temperature rise of resistors above the temperature of the cooling air when the test is made in accordance with the rating, shall not exceed 350 degrees Centigrade when the thermometer is placed in contact with the resistive conductor,* or 250 degrees Centigrade when the thermometer is placed in contact with the embedding material. The temperature rise of the issuing air, when measured one inch from the inclosure, shall not exceed 175 degrees Centigrade." Accordance with standard practice results in the rating of resistors to meet the above specifications. In addition, however, care must be exercised against the possibility of mechanical failure or excessive resistance variations, and these matters are considered in this section under the individual resistors.

Many instances arise where the natural convection currents of air, and heat conduction to other parts of the structure, do not remove the energy rapidly enough and the resistor temperature rises to excessive values. To aid in the dissipation of the excessive amounts of energy, forced cooling may be employed. This involves moving more cooling fluid past the resistor than would flow by natural convection, and for this purpose air, gas, water, oil, and other fluids may be circulated in an appropriate fashion over the resistor.

* The N.E.M.A. Standard states: " For bare resistive conductors the temperature rise shall not exceed 375 deg. cent. . . ."

CLASSIFICATION. The resistive conductors which have a general use in the construction of resistors are nickel, chromium, and iron usually combined to form an alloy, also molybdenum and platinum; non-metallic materials such as silicon-carbide compounds and carbon in various forms; and various liquids. The metallic resistive elements are prepared as wire, ribbon, or cast grids and are supported on various structures to give mechanical strength and electrical insulation and possibly to aid in energy dissipation by conduction (see Section 2, Materials). The materials which serve for supports in many forms are mica, micarta, sand, porcelain, pottery, lava, asbestos, vitreous enamel, and other compositions and refractories. The non-metallic resistor elements may be self-supporting, but carbon disks are usually supported in a tube from which they are electrically insulated. Liquids of various constitutions can be used for the dissipation of large amounts of energy, and various resistivities are secured by the use of different acids or salts. The solution is contained in an appropriate vessel, and the quantity used depends upon the energy to be dissipated.

The various elements noted above, assembled in the several forms of fixed and adjustable resistors, serve numerous applications. The commercial forms which these resistor elements take will be described in this section, for the applications in the power field. Precision resistors as used in laboratory precision measurements are considered in Section 5.

2. METAL ALLOY RESISTORS, NOT MOUNTED ON CERAMIC FORMS

CLASSIFICATION, DESCRIPTION, APPLICATION. This type of resistor consists of resistive elements in the form of grids, ribbon, or wire, supported on racks or panels and electrically insulated therefrom by mica, refractory, or composition. These elements may be built into groups to form a fixed resistance unit, or by means of connections, contact points, and a sliding contactor the resistance may be varied so that the device may serve for current adjustment in a connected circuit. For a given material, the resistance of a group of resistive elements may be changed by changing the physical dimensions of the individual elements, or the connection of the individual elements may be altered. Thus, placing elements in parallel will decrease the resistance across the terminals, and incidentally increase the current-carrying capacity of the device. The metal grid or ribbon resistors very readily supply the need for large-sized, relatively low-resistance units for large current-carrying capacities. Both the grid and ribbon may be built mechanically rigid, a characteristic not easily attained for coils or other forms of wire. Ribbon and wire are frequently used for heating and loading units, and in this application the elements are permanently assembled on a supporting frame.

The assembly of grid, ribbon, or wire resistors into a compact unit must follow certain definite considerations. After satisfaction of the resistance and current-carrying requirements there are the mechanical considerations. The elements must be spaced in such a manner that they do not touch each other. Long coils or spans of wire may have this defect, not possessed by rigid grid or ribbon. Spacing is also essential for the free movement of air past the elements to carry away the generated heat energy. It is essential that the element survive cycles of heating and cooling and physical shock, without cracking or breaking. Ribbon-type resistors have the advantage here, for they are generally unbreakable, can be assembled in a continuous strip, suffer no stress when expanded by heating, and weigh less in units of equivalent dissipation ratings.

Grids are built with a wide range of current ratings running from 15 to about 350 amp. Ribbon is constructed with a current rating up to about 25 amp. By paralleling units any desired current rating can be obtained.

The grid and ribbon resistor elements find their greatest use in applications requiring moderate and large current-carrying capacity such as for a-c and d-c speed regulation and starting of large motors. For these uses resistors are designed to comply with the American Engineering Standards. When correctly applied the resistors will operate with an average temperature rise not exceeding 350 deg cent. The A.E.S. Classification Table, Table 1, shows the service for which each class of resistors is designed together with the approximate starting torque and starting current obtained in the motors of one manufacturer. This table is the A.E.S. Table modified to include plugging resistors for steel mill service and resistors for dynamic braking in the off position, and also for dynamic braking while lowering for use on certain types of hoists.

RIBBON RESISTOR ELEMENTS. The size of the grid or ribbon type resistor when assembled in a fixed or adjustable resistance unit varies widely depending upon the amount of auxiliary equipment and the complexity of the assembly. Typical of the simple ribbon resistor are the weights given in Table 2 for various groups of units pro-

Table 1. A.E.S. Resistor Service Classification (Courtesy Westinghouse E. & M. Co.)

Percentage Full-load Current on 1st Point of Controller	Starting Torque in Percentage of Full-load Torque					Resistor Classification Number				
	D-C Motors			Wound Rotor Motors		Starting Duty		Intermittent Duty		Continuous Speed-Regulating Duty
						Light	Heavy	Light	Heavy	
	Series Motors	Compound Motors	Shunt Motors	Single-phase Starting	Three-phase Starting	15 Seconds on out of 4 Minutes	30 Seconds on out of 4 Minutes	1 Minute on out of 4 Minutes	2 Minutes on out of 4 Minutes

* The letter V indicates that the resistor is designed for varying torque applications where the horsepower varies approximately as the cube of the speed.
† The letter D indicates additional capacity for dynamic braking while lowering.
‡ The letter P indicates additional capacity for plugging service.
§ The letter B indicates additional capacity for dynamic braking in off position.

duced by one manufacturer. The ribbon is best in zigzag shape and held between porcelain blocks which have recesses for each bend of the ribbon. The blocks are securely interlocked in steel channels which are fastened together at the end to form unit resistors of different lengths. The tabulation is shown for assemblies made up of different unit resistors No. 3, 4, 5, and 6. Each No. 3 unit when frame assembled with other, similar units occupies a volume of about the dimensions 16 by 3 by 6 1/2 in. The other units are longer (20, 24, and 28 in., respectively) but have similar dimensions otherwise.

3. METAL ALLOY RESISTORS, MOUNTED ON CERAMIC FORMS

This type of resistor is produced in two general forms. In the first, the resistor elements are imbedded in a refractory material and supported by it, sometimes in conjunction with a metal plate. In the second form the resistor ribbon or wire is wound around an insulating form, which generally has a cylindrical shape.

FIXED RESISTANCE UNIT. The first of these forms (resistance wire imbedded in refractory) is generally produced as a heater unit. Encased in sheaths of rust-resisting

iron or heat-resisting chrome steel, these units can be carried to high temperatures for air heating or for use in all types of appliances such as ranges, incubators, and melting pots. Such forms likewise are applied to the heating of liquids in the immersion-type unit. One manufacturer gives the relation shown in the curve of Fig. 1 below, for the watts rating of the strip type heater for different heater temperatures.

Since there are approximately 3 1/2 sq in. of surface per inch of heated length of this type of unit a calculation will show the relation between the watts per square inch and the temperature of the radiator surface. If it is assumed that the resistor unit rises in temperature above an ambient value of 70 deg fahr, a calculation may be made of the temperature rise per watt of power for each square inch of surface. The result of this

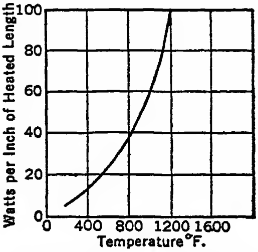

FIG. 1. Operating Temperatures of a 1 1/2-inch Strip Heater Element, Operating in Horizontal Position in Still Air. (Chromalox—Courtesy E. L. Wiegand and Co.

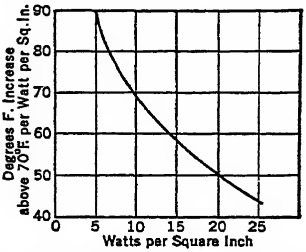

FIG. 2. Temperature Rise above 70° F of a 1 1/2-inch Strip Heater Element, per watt per sq. in. for Various Rates of Energy Dissipation

calculation is shown in the curve of Fig. 2, which indicates that the temperature increment per watt per square inch decreases with increasing heat dissipation. Approximately the same values under similar temperature conditions will be found in the various other types of imbedded resistor including the plate type and vitreous tube type.

PLATE-TYPE RHEOSTAT, CONSTRUCTION. The "plate-type" rheostat has a very general use for small and moderately sized current regulation requirements such as in motor starting, field current regulation, lamp circuit dimming, battery charging, and other uses. Probably the most widespread use occurs in the control of field current in d-c machines. The adjustable resistance type of unit is the general form, and is built up in the following steps on a "plate" of metal or some insulating material. Using a pressed steel plate as a base this plate is sandblasted on one side to remove foreign particles and to provide a softly roughened surface. A ground coat of vitreous enamel is then baked on this surface of the plate, protecting this surface and forming an electrical insulating but heat-conducting layer. The resistance wire used in the plate type rheostat is first crimped into a "wave" form. Various lengths of this wave wire are attached between the metal buttons which subsequently serve to contact the moving contact arm. As the wire is very springy it must be held in a form during its assembly and spot-weld connection to the buttons. While still on the form, the wire is heated and annealed to remove its springiness. The resistance wire and button assembly are then carefully spread on the prepared plate and baked in enough vitreous enamel to securely cover and hold the wire in place. The coating likewise serves to prevent corrosion and mechanical injury, and it aids in conducting away the generated heat. The last step in the manufacture is the cleaning and leveling of the contact buttons and the assembly of contact arm, mounting, and other auxiliary parts. An important test which must be passed by this type of unit is that the resistance wire circuit be continuous, not grounded to the metal base plate, and with the proper resistance value between adjacent buttons.

RHEOSTATS, GENERAL. This last point is an important one for all types of adjustable resistance devices. With the motion of the contact arm from one contact point to the next it is desired to change the resistance in the circuit by a definite number of ohms, or perhaps a definite percentage. Depending upon the type of circuit, the resistance between points may be uniform around the rheostat or may taper according to some particular design. Generally, the motion of the contact arm is accompanied by a change of current through the rheostat. It is seen from this that the current-carrying capacity of the various intercontact points need not be the same, and for this reason, rheostats are generally constructed with a current rating which varies from point to point on the rheostat. This must be given consideration in both the plate and box-type rheostat with the careful design of grid, ribbon, wire in vitreous enamel, or on open form units, to suit the particular circuit need. The combination of different resistance values

and different current values will result in a variable wattage rating at different points about the rheostat. In the usual construction the resistor elements are mounted on a supporting insulated plate on which are also mounted the contact buttons, contact arm, and other auxiliary equipment. For certain applications the resistor elements are surrounded by a metal enclosure filled with sand. The sand aids in supporting the elements and in the conduction of the heat energy from the resistor. The thermal conditions are different from those surrounding resistors in free air, and this must be considered in the design of the rheostat.

The assembly of the adjustable resistance rheostat, in many of its uses, requires considerable auxiliary equipment including contact arms, no-voltage release, overload circuit breaker, equipment for manual or motor operation, mounting, and case, and these variations are numerous and cause wide ranges in design. Specific information on these matters is given in Section 12 on Control and Protective Equipment.

WOUND VITREOUS ENAMELED UNITS. This type of unit finds its use where a resistor of relatively small capacity and of fixed value is needed. Certain variations on the main type are in use for special purposes, but generally the unit consists of a single winding running from one end to the other on a cylindrical ceramic tube. For power applications this type of unit is used primarily to dissipate small amounts of energy. The major application is found in the communication field where the vitreous enamel unit serves as a voltage divider in radio receivers and other equipment. Some application of this type of unit has been made in the construction of small rheostats.

WINDING. Windings on refractory porcelain tubes vary in wire size from strap down to diameters of about 0.002 in. This winding when imbedded in its protective coat of vitreous enamel reaches fairly high temperatures. For the maintenance of a small tolerance in resistance variation the wire should have a low temperature coefficient (see Section 2, Art. 6). The standard resistance tolerance on standard vitreous enamel resistors is $\pm$ 5 per cent. The temperature coefficient of expansion is likewise important for this type of resistor. Expansion and contraction in the winding and porcelain tube with temperature change should be similar so that the winding will not tear away from the tubing or be unduly stressed. The winding is run on the tube with the use of a lathe and automatic pitch setting. It is customary in resistors of this type for the units to be wound substantially full with wire of such size that the winding pitch will not be less than twice the wire diameter. Terminals are then applied to the ends of the winding, and to any tap points along the winding. Terminals of copper, monel metal, or some other alloy are secured to the ends of the winding usually by mechanical interlocking and then by brazing with special alloys or silver. The terminals are produced in many forms including lug type, flexible leads, ferrule type, cartridge type, A.R.A. unit type, and standard Edison base units.

VITREOUS ENAMEL COATING, ON WOUND UNITS. Certain requirements are of importance for the vitreous enamel used to coat the wound resistors. The primary requirements are that the coat should protect the wire and provide a conducting path for the heat generated in the wire to the outside air. In addition the vitreous enamel must maintain its insulation strength and must be moisture and corrosion proof. To maintain these latter characteristics the thermal expansion and contraction of the coating should be as nearly as possible equal to those of the winding and of the refractory base. This will aid in preventing chipping and cracking of the enamel. The unit is subjected to a red heat during the process of firing the enamel, and after cooling, the enamel should completely cover the winding and hold it in place without any mechanical strain, and should be free from bubbles or other imperfections.

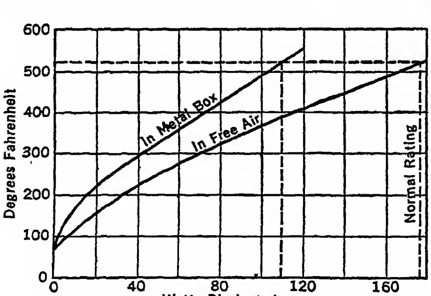

FIG. 3. Effect of Enclosing Vitreous Enameled Resistor in Metal Box. Unit when mounted in metal box reaches maximum temperature when dissipating only about 62 per cent of normal rating. (Courtesy Ohmite Mfg. Co.)

VITREOUS ENAMEL UNIT RATING. According to the construction of each unit, it is given a "normal rating" which is based on the assumption that the resistor, when mounted, will be surrounded with at least 1 ft of free air space, and that the circulation of air will be unrestricted. When so mounted the vitreous enameled resistor will dissipate energy at approximately 7 watts per square inch of surface area with a tem-

perature rise of not more than 250 deg cent when the temperature of the cooling medium does not exceed 40 deg cent. This is in accordance with the Standards of the National Electric Manufacturers Association. Whenever resistor units are mounted in a small enclosed space where air circulation is limited, the units should not be submitted to "normal rating." Where such conditions exist (say if the resistor operates in an enclosure), or if the resistor is submitted to over-rating surges, or one or more taps are built in, the unit should be worked at half or even quarter normal rating. The effect of enclosing, on the temperature of the hottest point (at the middle of the resistor) of a vitreous enameled resistor, is shown in the curves of Fig. 3. For operation in a metal box it is seen that a unit dissipates only 62 per cent of normal rating before reaching the maximum temperature.

VITREOUS ENAMEL UNIT, DIMENSIONS. Standard vitreous enameled units are made in a very wide range of resistance values and in normal ratings up to about 250 watts. A representative line of resistors is given in Table 3 along with approximate dimensions. Units may be had with various terminals, various numbers of taps, or adjustable taps, at slightly higher cost.

Table 3. Approximate Dimensions of Vitreous Enameled Resistors

Normal Rating, watts	Made in Units of Resistance, ohms	Approximate Size, inches Diameter × Length
5	1 to 10,000	1/4 × 1
10	1 to 30,000	3/8 × 1 3/4
20	5 to 100,000	1/2 × 2
30	5 to 100,000	5/8 × 3
50	10 to 100,000	5/8 × 4
75	100 to 100,000	5/8 × 5
100	25 to 100,000	7/8 × 6 1/2
200	25 to 100,000	1 1/4 × 8 1/2

SPECIAL FORMS. Low-resistance vitreous enamel resistors intended for heavy duty generally employ a strip of ribbon for the resistor element instead of wire. In this type the metal alloy resistance ribbon is wound on edge on the refractory tube. The support of the ribbon may be derived from grooves in the core, or the ribbon may be crimped into a wave form thus supporting itself on edge. In the latter case it is the practice to cover the element partially with vitreous enamel, holding the element in place and aiding in the heat dissipation. The fin-like form of the ribbon brings considerable area into contact with the cooling air. Both the enamel covered and uncovered units with edgewound resistors find their primary application in moderate rating power uses. Individual units are rated up to about 500 watts for continuous duty, and in proper combinations they serve for starting and control on motors up to about 50 hp.

Many applications of the wire-wound resistor require that the resistance from one unit be semi-variable. In the vitreous enamel unit a narrow contact strip along one side is not covered with enamel, and free contact with the resistance wire is possible. An adjustable lug is pressed into contact with the winding at the desired point, and together with the end terminals constitutes a three-terminal resistance. These units may be had in total resistance values of 1 to 100,000 ohms and in ratings up to 200 watts.

A refinement of the above resistor form appears in the sliding contact tubular rheostats which are designed for accurate control of currents up to about 25 amp. The winding is usually mounted on a glazed porcelain tube although an iron tube surfaced with vitreous enamel is sometimes used. Oxidized resistance strip or wire is used on the tube, the oxide providing insulation between the turns. A slider bar, mounted above the tube, supports laminated phosphor-bronze contact brushes, which make contact on the winding surface. Fine resistance adjustment may be effected by use of a micrometer drive, and for rough adjustment the slider is moved by hand. Such units may serve as rheostats or potentiometers according to connections and have wide application in laboratory and precision measurements. The various units obtainable range from about 0.4 to 40,000 ohms, in current-carrying capacities from 25 amp down to 0.1 amp.

Among the many other special forms of resistors for power use there is the current-limiting resistor for potential transformer fuses. This type of resistor is intended for use in series with potential transformer fuses to limit the short-circuit current, in case of short circuit, to such values that the fuses will interrupt the circuit safely. The resistors are of the wire type and consist of coiled nickel-chromium wire, wound in grooves of a heavy wet-process porcelain tube. These units are built in resistance values up to 225 ohms for voltages up to 25,000 volts.

4. NON-METALLIC RESISTORS

COMPOSITION TYPE. For industrial applications in the power field composition resistors are usually made of some silicon carbide composition, and used in rod or tube form as a resistance heating element or for special applications. The chief advantage of this type of resistor is that it can be operated continuously at temperatures up to about 2400 deg fahr which is above the permissible safe range of nickel-chromium resistors. The " Globar " type of resistor can, therefore, dissipate heat at a greater rate than a metallic resistor, and dissipation rates of 5 to 10 kw per sq ft are possible with the elements mounted adjacent to or in contact with refractory surfaces. This is about twice the safe rate for metallic resistors under similar conditions. The composition rod resistor manufactured under the name of Zircon may be used in all types of circuits where a non-inductive resistance is required. Its applications are numerous and include uses as resistor in series with potential transformer fuses; as relay shunts, for all purposes in surge testing circuits; for all d-c and a-c testing outfits; as charging resistors for electrolytic lightning arrestors; as high-resistance shunts for power-limiting reactors and many others. Zircon rods are manufactured in resistance values from 20 to 1,000,000 ohms, and although they may be run at temperatures as high as 150 deg cent they are not intended for use as heater units, and energy will be dissipated at only about 100 watts in the 1 by 12-in. rod.

CARBON RESISTORS. Carbon resistors with fixed resistance values find wide application in the field of radio communication and are therefore considered in the volume on Electrical Communication under "Resistors." Carbon rheostats, however, have considerable use for current regulation in many types of power circuits including the use as manual or automatic motor starting equipment. The carbon rheostat is generally made up of plates of carbon enclosed in a refractory-lined steel tube or frame. The variation of resistance is effected by applying varying degrees of pressure on the column of graphite disks. This varies the numerous points of contact between the individual disks and produces a contact resistance variation inversely as the pressure applied. The resistance of the column consists almost entirely of the contact resistance between the disks, and the graphite disks serve merely as contactors and heat dissipators. The advantages claimed for this type of compression rheostat include stepless control, durability, high overload capacity, wide resistance range amounting approximately to 75 to 1, freedom from sliding contacts, and full wattage capacity at any resistance setting. Applications of these characteristics range from battery-charging installations to the starting and control of 500-hp motors. Such control applications are discussed in Section 12.

LIQUID RHEOSTATS. Water as from the tap supply or containing small quantities of a salt, acid, or base may be used as an electrical resistance. Some of the substances which have been used are $NaCl$, NH_4Cl, KOH, and H_2SO_4. The device may serve as a rheostat by the movement of one electrode with respect to the other. A single phase load of 100 amp at 100 volts may be carried continuously in a 40-gallon barrel without causing the water to boil. The plates should have a surface (one side only) of at least 1 sq in. per amp.

CAPACITORS—CONDENSERS

An electric condenser is a device the primary purpose of which is to introduce capacitance into an electric circuit. It consists essentially of two conductors with their surfaces relatively close together, separated by an insulating medium called the dielectric. The dielectric is that part of the condenser which is mainly responsible for the properties of the condenser itself. The characteristics of materials generally used as dielectrics are presented in Section 2, Materials. The action of the condenser as a circuit element is presented in Section 3.

5. PROPERTIES OF CONDENSERS

CLASSIFICATION. Condensers are usually classified in terms of the material used for dielectric. This classification serves readily to distinguish most condensers, but two special forms must be considered separately. These are the synchronous condenser and the electrolytic condenser. The synchronous condenser is a synchronous motor operated with its excitation so adjusted that it has the properties of a condenser. It is operated in this manner for power-factor correction on transmission lines. A discussion of the synchronous motor in this and other applications is given in Section 9, A-c Generators and Motors. To distinguish condensers used for power factor correction, not of the synchronous machine form, the classification " static " is given. This classification may well include all condensers without moving parts. The other special form of condenser is the electrolytic. The capacitance action of this cell arises from the formation of an extremely thin insulating layer at the anode on an electrolytic cell. The insulating layer serves as the dielectric between the metal anode and electrolyte which are the "plates." This form of condenser has its major application in power supplies for radio receivers. It will therefore be discussed in the volume on Electrical Communication.

Classification of condensers according to the dielectric used between the conducting plates will form a division into the following groups: (1) impregnated paper condensers, (2) mica condensers, (3) glass condensers, (4) condensers with a fluid dielectric (oil, air, etc.). This classification might be extended to include the listing of practically every insulating material known. Those noted above are, however, the most important and the most widely used. In order to understand the factors in the design and use of these condensers, the development of some of the important condenser formulas will be given. Condensers may be divided into two other broad groups—those with fixed capacitance (generally solid dielectric such as impregnated paper, or mica) and those in which the capacitance can be varied. The latter generally have fluid dielectrics (air, oil) and have wide use in radio circuits. The characteristics of the variable condenser will therefore be treated in the volume on Electrical Communication under " Condensers." The following development applies particularly to solid-dielectric fixed-capacitance condensers.

CAPACITANCE. The capacitance, which is a measure of the electrical charge that a condenser will retain under a given potential, depends upon three factors: the area of the dielectric separating the plates, the thickness of the dielectric, and its specific inductive capacity (dielectric constant). When the two conducting plates are parallel, close together, and of large area, as in most paper, mica, and glass condensers, the capacitance is given by the expression,

$$C = 0.0885 \times 10^{-6} KS/\tau$$

where C is in microfarads, S = area of one side of one conducting plate in square centimeters, τ = thickness of dielectric between the plates in centimeters, and K the dielectric constant (= 1 for air and between 1 and 10 for most ordinary substances). This formula assumes that the charge is uniformly distributed over the surfaces of the conductors, no corrections being made for edge or end effects. It is seldom worth while, however, to apply a correction on this account, because the capacitance to the condenser case or other conductors is ordinarily not calculable, so that the actual capacitance of a condenser can be calculated only approximately. The actual value is likely to be in excess of that calculated. When very accurate values are required they must be obtained by measurement.

POWER LOSS. In an ideal condenser, the conductors or plates would have zero resistance and the dielectric infinite resistivity in all its parts. If an alternating emf is applied to such a condenser, a-c current will flow into the condenser. At the moment when the emf is a maximum no current will be flowing, and when the emf is zero the current will be a maximum. Hence, in a perfect condenser the current and voltage are 90 deg out of phase. In actual condensers the conditions as to resistance in the plates and dielectric are not fulfilled, and in consequence an alternating current flowing in a condenser is not exactly 90 deg out of phase with the impressed voltage. The difference between 90 deg and the actual phase angle is called the " phase difference " or phase defect angle. In an ideal condenser there would be no consumption of power; the existence of a phase difference means a power loss, which appears as a production of heat in the condenser. The amount of power loss is given, as for any part of a circuit, by $P = EI \cos \theta$, where θ is the phase angle between current and voltage and $\cos \theta$ is the power factor. This is equivalent to

$$P = EI \sin \psi$$

where ψ is the phase difference and $\sin \psi$ is the power factor of the condenser. In all except extremely poor condensers, ψ is small, $\sin \psi = \psi$, and thus the phase difference and power factor are synonymous. The power loss is given by $P = \omega CE^2 \sin \psi$. This shows that, for constant voltage, the power loss is proportional to the frequency, to the capacitance, and to the power factor. The power loss in a condenser may be due to either imperfection of the dielectric or to resistance in the metal plates or leads. The dielectric may cause a power loss either by current leakage, by brush discharge, or more commonly by the phenomenon described later under the head of "Dielectric Absorption."

LEAKAGE. The leakage of electricity by ordinary conduction through the dielectric or along its surface contributes to the phase difference at low frequencies. The effect of leakage on the power factor may be seen as follows: A condenser having leakage may be represented by a pure capacitance with a resistance in parallel. The current divides between the two branches, the current I_r through the resistance being in phase with the applied E, and the current I_c through the capacitance leading E by 90 deg. The resultant I leads E by an angle which is less than 90 deg by the phase difference ψ. From Fig. 1, $\tan \psi = \dfrac{1}{r\omega C}$.

The effect of r may be shown by an example. A condenser of 0.01–μf capacitance with an insulation resistance as low as 10 megohms has, at a frequency of 60 cycles per second, a power factor $= \dfrac{1}{(10)^7\, 377 (10)^{-8}} = 0.027 = 2.7$ per cent. This is a very appreciable quantity; 2.7 per cent of the current flows by conduction instead of by dielectric displacement. This effect, however, decreases as the frequency increases, for the dielectric current increases in proportion to the frequency while the leakage current does not. For instance, at 10,000 cycles, the power factor = 0.00016.

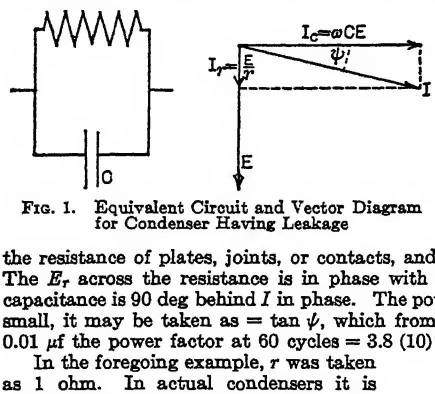

Fig. 1. Equivalent Circuit and Vector Diagram for Condenser Having Leakage

SERIES RESISTANCE. A resistance within a condenser in series with the capacitance affects the power factor very differently from a resistance in parallel. The series resistance includes the resistance of plates, joints, or contacts, and the leads from binding posts to plates. The E_r across the resistance is in phase with the current I, and the emf E_c across the capacitance is 90 deg behind I in phase. The power factor $= \sin \psi$, and since ψ is usually small, it may be taken as $= \tan \psi$, which from Fig. 2 is $r\omega C$. If $r = 1$ ohm and $C = 0.01\ \mu$f the power factor at 60 cycles $= 3.8\,(10)^{-6}$. This is a negligible quantity.

In the foregoing example, r was taken as 1 ohm. In actual condensers it is sometimes greater than this. A plate resistance of several ohms is common in the ordinary paper condenser. In most other condensers, a high series resistance indicates a defect.

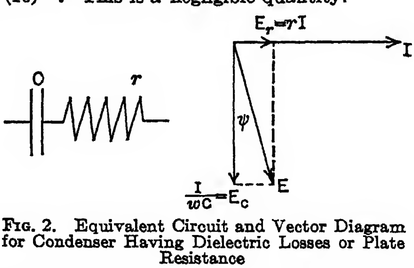

Fig. 2. Equivalent Circuit and Vector Diagram for Condenser Having Dielectric Losses or Plate Resistance

DIELECTRIC ABSORPTION. When a condenser is connected to a source of emf such as a battery, the instantaneous charge is followed by the flow of a small and steadily decreasing current into the condenser. The additional charge seems to be absorbed by the dielectric. Similarly, the instantaneous discharge of a condenser is followed by a continuously decreasing current. It follows that the maximum charge in a condenser cyclically charged and discharged varies with the frequency of charge. The phenomenon is similar to viscosity in a liquid, and is sometimes called dielectric viscosity.

Dielectric absorption is always accompanied by a power loss, which appears as a production of heat in the condenser. Since energy is expended in the periodic stressing of the dielectric material, the phenomenon is similar to magnetic hysteresis in the ferrous metals. It therefore is frequently termed dielectric hysteresis. The existence of a power loss signifies that there is a component of emf in phase with the current. The effect of absorption is thus equivalent to that of a resistance either in series or in parallel with the condenser. It is found most convenient to represent absorption in terms of a series resistance, which is spoken of as an equivalent resistance of the condenser. An absorbing

condenser is, therefore, considered from the standpoint of Fig. 2 and the power factor $= r\omega C$. The equivalent resistance r is constant for a given frequency but is different for different frequencies.

EQUIVALENT SERIES RESISTANCE. In the foregoing paragraphs it was seen that losses in a condenser could be classified under the following heads:

1. Leakage of current through or around the dielectric, appreciable when the insulation resistance of the material is low.
2. Actual conductor series resistance of leads, connections, and the plates themselves.
3. Dielectric absorption or hysteresis.
4. Corona from plate edges, important at high voltages.

In the discussion, the effect of each of these, with the exception of corona, has been individually shown on the power loss and power factor of the condenser. In practice, all the losses exist to some degree and each contributes to the power loss of the condenser. Generally, it is difficult to determine the individual losses separately, and therefore for any given set of conditions they are determined together. Grouping these effects, we attribute the losses in the condenser entirely to an "equivalent series resistance." This is indicated in Fig. 3. Except when insulation resistance is intended, a discussion of the "resistance" of a condenser always means the equivalent series resistance. The value of this resistance when multiplied by the square of the alternating current flowing in the condenser represents the rate of energy consumption in the condenser. Repeating the expression for power in a condenser

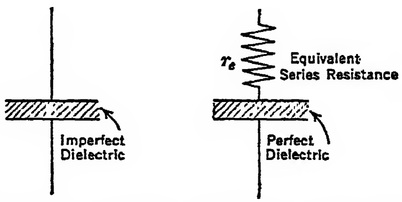

FIG. 3. Equivalent Circuit of Actual Solid Dielectric Condenser Showing all Loss Effects Lumped into One Equivalent Series Resistance

$$P = \omega CE^2 \sin\psi = I^2 r_{\text{equivalent series}}$$

DIELECTRIC STRENGTH. When the leakage of electricity by conduction through the dielectric becomes excessive, the dielectric ceases to be an insulator and breakdown occurs. The leakage, in any given material, depends upon the voltage on the plates, the shape of the dielectric, its size, homogeneity, and temperature. For any given dielectric under a set of physical conditions there is a limiting voltage beyond which the dielectric strength of the material will be exceeded. See Sect. 2, Art. 9.

COMPARATIVE MERITS OF DIELECTRICS. In a comparison of dielectrics the following characteristics are of importance and must be considered as under the conditions of intended use: (1) the physical constitution of the material (fluid, solid); (2) the dielectric constant; (3) the power factor; (4) dielectric strength. The product of the dielectric constant and the power factor is sometimes used as another means for comparing dielectrics. From the expression previously stated for the power loss in a condenser, $P = E^2\omega C \sin\psi$. When the phase difference angle of the condenser is small, $\sin\psi = \psi$. If V is the volume of dielectric used, E the voltage across it, f the frequency, K the dielectric constant, ψ the phase difference, P the power used in the dielectric due

Table 1. Dielectric Data*

Approximate Low-Frequency Characteristics

Material	K	Power Factor $10^4 \times \tan\psi$	KV eff. per centimeter

to dielectric hysteresis, and m a constant depending upon the various units employed, the above expression becomes

$$\frac{P}{V} = mE^2f(K\psi)^*$$

Thus, the product $K\psi$ gives a measure of the relative merits of two dielectrics so far as power loss is concerned, and it is called the loss factor.

MEASUREMENT OF CONDENSER CHARACTERISTICS. Measurement of any condenser characteristic should always be made, if possible, under the same physical and electrical conditions as will later surround the actual use of the condenser. Temperature, humidity, atmospheric pressure, the surroundings of the unit under test; the circuit voltage, wave form, and frequency all have some effect on the various characteristics (see Section 5). It should be carefully noted that none of the " constants " of a condenser are constant. As the above conditions vary, condenser capacitance, power factor, equivalent series resistance, and the dielectric insulation resistance, dielectric constant, and breakdown strength all vary. These variations have major importance in many applications of condensers both in the power and communications fields of development.

6. CONSTRUCTION AND FIELDS OF APPLICATION

The choice of a condenser for a particular application is governed by several considerations of an economic and electrical nature. Usually the first consideration is the amount of capacitance required in the unit to be constructed. Then, the voltage across the condenser, and the circuit frequency must be determined. With these known the current flow through the condenser is calculated. For a given set of electrical conditions the questions next answered are: In how much volume can this condenser be built? Are there any restrictions as to size? The variation of any one of these factors affects practically all the others, and dominating all, is the factor of condenser cost. To build a condenser for high voltage requires the use of a pure, uncontaminated dielectric of the requisite high dielectric strength. To build a small condenser requires the use of a thinner dielectric, of high dielectric constant and the requisite dielectric strength. To build a condenser in which the capacitance will be unaffected by humidity, and which will remain constant, requires special care in impregnating and encasing. To build a condenser in which the capacitance of all the units is practically the same with set limits of tolerance requires uniform material and uniform processing. All these factors, affecting as they do the choice of dielectric, the impregnation of the dielectric, and the assembly of the components essentially determine the cost of a condenser. The various factors are weighed against each other and a final selection made.

CONDENSERS WITH PAPER DIELECTRIC. More units of this type of condenser are produced and put in use each year than of any other type. The materials of construction and the variety of forms permit a wide range of quality, and therefore, cost. The field of telephone communication has the most extensive use for this type of condenser. The paper condenser is practically always produced as a fixed capacitance winding of some metal foil interleaved with one or more sheets of impregnated paper. Such rolls of multiple layers of foil and insulation build up a comparatively large capacitance in relatively small volume. The unit is usually encased in a metal or cardboard container to protect it from mechanical damage. The paper used as the insulating dielectric between the foil plates must be thin, uniform, and continuous, must be neutral chemically and free of conducting particles. The paper usually is 0.5 mil thick, but to secure further decreases in size a 0.4-mil paper is extensively used. The paper is usually impregnated with some compound to give it a higher effective dielectric constant in the finished state. The most common impregnating material has been paraffin. Many other oils and preparations are in use, and a chlorinated naphthalene, commercially known as halawax, has shown excellent characteristics for this service.

Materials most generally used as conductors include tin foil, aluminum foil, and metallized paper. Aluminum and tin foil are prepared in thicknesses down to 0.25 mil. Aluminum foil is more desirable generally, being lighter, but it is more difficult to solder. Metallized paper or Mansbridge condensers use an extremely thin sheet of foil deposited on the paper to form a conducting plate. In this type of condenser, should a dielectric failure occur, the thin metal surface around the fault vaporizes and the fault is usually cleared. This self-healing is a most valuable characteristic and usually possible only in fluid-dielectric condensers. The very thin conductor plates, however, lead to high conductor resistance and do not readily permit the construction of a non-inductive winding.

---

* After Hoch, *Bell Sys. Tech. J.*, November, 1922.

The assembly process consists of rolling the two sheets of metal foil, and in one particular case, four sheets of paper so that the completed unit will have two layers of paper between adjacent sheets of tin foil. The winding may be either inductive or non-inductive. Inductive windings use foil which is about 0.5 in. narrower than the paper. The section is wound up with equal paper margins on each side. Tinned copper strips are laid in at the end of the winding to enable a connection to be made. The non-inductive winding uses foil the same width as the paper, foils of opposite polarity protruding about 0.25 in. on the opposite edges of the winding. High-frequency applications usually require the non-inductive winding, and this type of winding facilitates heat dissipation by thermal conduction through the electrical connections. In such a condenser the maximum distance the charging current has to flow is the width of the foil, whereas in the inductive winding the charging current must run the whole length of the winding.

After winding, the unit is pressed into compact shape and then while still in a high vacuum (approximately 0.25 in. mercury) is impregnated with the oil or wax. If the air were not completely removed the effective dielectric constant of the insulating medium would be small owing to the effect of the low dielectric constant of the air. Moisture in a condenser very seriously increases its losses, and therefore both air and water vapor are carefully removed. After impregnation the unit is pressed to the required size, forcing out the excess wax or oil, and the soldering lugs are fastened to the metal contact strips which are in contact with or soldered to the sheets of tin foil. If, during the cooling of a wax impregnated condenser, the surface coating cracks, moisture and air will re-enter and spoil the condenser. The ends of the cooling condensers are sometimes covered with a layer of soft non-cracking wax to prevent this. The unit is then ready for potting in a metal container. These are partially filled with a sealing compound, which, when the condenser units are inserted, completely fills the container and seals the condenser against all entrance of moisture. This sealing compound likewise performs the valuable function of conducting the condenser energy dissipation to the outside cooling can and air. The condenser is now ready to withstand severe conditions of continuously applied voltage, high humidity, high temperature, and mechanical abuse.

Since 1926 the standard condensers produced by the Western Electric Company have gone through considerable development. With the increased use of hydraulic press, power winding, prepressing, and automatic sorting, and with the development of aluminum foil, thinner papers, and the new wax, the cost of manufacture of a unit has been about halved. At the same time the volume of the standard 1-μf unit in container has been decreased from 5.85 cu in. to 1.84 cu in. The winding length which was 238 in. in 1926 is reduced to only 95 in.

A paraffin-impregnated condenser using a good grade of 0.5-mil paper will stand from 100 to 200 volts for each layer of paper used. For high voltages it is necessary to use as many layers of paper as are necessary to withstand the dielectric stress. With dielectric loss occurring in a condenser when it is used in an a-c circuit, it is necessary to rate the condenser for a lower alternating voltage than would be permissible in a d-c circuit. Since at high frequencies the voltage across a condenser (for any current) becomes less, it is necessary to rate the condenser in terms of safe heating of the dielectric. This requires that a current limitation be placed on the use of the condenser, and obviously the safe volt-ampere rating will vary with frequency.

In a well-made impregnated-paper condenser the insulation resistance will be from 100 to 1000 megohms per microfarad. Since insulation resistance varies inversely as the capacitance of a condenser, the smaller condensers will have greater insulation resistance. Manufacturing specifications have set definite limits on the insulation resistance for condensers in certain uses. For instance, the N.E.M.A. Standard 334–216 states "... the insulation resistance shall not be less than 500 megohm-microfarads, at a capacitor temperature of 68° F (20° C)." This particular standard applies to fixed paper condensers used in power supply circuits for radio equipment.

Table 2 represents the construction practice of one manufacturer of condensers:

CONDENSERS WITH MICA DIELECTRIC. Mica as a condenser dielectric has established itself as one of the most efficient materials for use in fixed low-capacitance but high-voltage condensers. When pure, it has a very low dielectric loss, but it acts as a fair adsorbent of water. Even a thin layer of water only one molecule thick on the faces of the mica will enormously increase its dielectric loss. Mechanical injuries such as surface scratches or any disturbance of the crystalline structure will cause very large dielectric losses. The assembly of mica dielectric and metal foil sheets as a condenser follows the main steps in the similar process for paper-condenser manufacture. The mica condenser, however, is made of alternate flat sheets of insulation and foil and is not rolled. Built for high voltage, a mica condenser consists of a combination of individual condensers called sections. These are connected in series forming stacks, which may be

Table 2. Insulation and Voltage Specifications
For Paper Condensers

Maximum D-c Working Voltage	Maximum A-c Working Voltage	* D-c Retest Voltage	Total No. of Papers	No. of Papers between Plates	Thickness of Each Paper, mils
200	125	400	4	2	0.5
300	175	600	6	3	0.4
400	250	800	6	3	0.5

1000	600	2000	6	3	1.0

* N.E.M.A. Standard 334–111: "The standard voltage test for paper capacitors shall be a single application of two times the working voltage—and the immediate discharge through a resistor of sufficient ohmic resistance to limit the discharge current to not more than 1 ampere, the entire cycle of operation not to exceed 15 seconds."

connected in parallel with other stacks. A section is made of a definite number of sheets of mica and a number of metal foils. The usual form and size of the mica is a rectangle about 1.5 in. square, and generally not over 2 by 3 in. Thicknesses of 1.0 mil to 4.0 mils are used. The foil area is correspondingly smaller to allow for at least $^1/_8$-in. margin. Odd and even foils protrude on opposite sides of a section, and the foils of like polarity are soldered together. After moisture and air are driven off, the stacks are adjusted for capacitance, encased, and clamped. The many small mica units which have extensive communication circuit use are encased in molded Bakelite. Metal containers, however, are used for the larger units and for high-voltage work usually require insulator bushing terminals of high dielectric strength. For a mica condenser to hold its accuracy, have no drift with time, and not vary with atmospheric conditions, the case of the condenser must be moisture proof and maintain a constant pressure on the condenser unit. For precision work this requires some constant-pressure device, pressing on the sections at all times. Mica condensers serve extensively in high-voltage circuits for both the power and communication fields. Among these uses there are the radio transmitter, high-frequency furnace circuits, and carrier current communication systems. Their use in small sizes, either fiber or molded Bakelite encased, in radio receivers is very extensive.

CONDENSERS WITH GLASS, RUBBER AND OTHER SOLID DIELECTRICS. As in the mica and paper condensers, numerous other solid dielectrics are used in the construction of fixed condensers. Perhaps the most familiar of these is the historic Leyden jar in units of 0.002 to 0.004 μf. This consists of an open-mouthed cylindrical jar usually with an inner and outer surface coating of foil or copper. These have had extensive use and exist now in numerous special forms. Moscicki's modification of the Leyden jar diminished the loss in this type of condenser due to brush discharge. This was accomplished by increasing the thickness of the dielectric near the edges of the metal coatings. Another modification submerges the whole jar in oil to reduce brush discharge loss. The materials suggested in the above heading along with many others are generally used as insulators separating the moving from the fixed plates in a variable-capacitance condenser.

CONDENSERS WITH FLUID DIELECTRICS. Air and various inert gases and certain mineral and vegetable oils are used as dielectrics in condensers. It has already been seen that wax and oil improve the dielectric constant of paper in a condenser. Between the supported plates of an air condenser a good oil will permit a high voltage, will have a low brush and dielectric loss, and usually will have a relatively large dielectric constant. The last feature permits a smaller condenser for a given capacitance. Precisely the same effects result when air or an inert gas is compressed and serves between open plates. The breakdown voltage becomes very high; as much as 35,000 volts may be used between plates spaced 3 mm apart. Fluid-dielectric condensers have their major use where a continuously variable capacitance is desired. Inert gas under pressure is occasionally used to permeate the paper or linen dielectric of high-voltage condensers used for power-factor correction.

ELECTROLYTIC CONDENSERS. The electrolytic condenser has a most extensive use in the field of communications, and a complete discussion of its characteristics is given in the volume on Electrical Communication. However, numerous applications have been developed in the industrial field and include use as a filter condenser, in spark suppression and noise filters on d-c contactors, circuit breakers, commutators, motors, and other d-c apparatus. A brief description of the major characteristics follows:

Certain metals, notably aluminum and tantalum, when placed as anodes in a suitable electrolyte, become coated with a film having unusual electrical properties. Films formed in this manner are characterized by the influence of impressed potential on their electrical resistance. This resistance imparts to the film the capability of conducting current more freely in one direction than in the other; of breaking down as an insulation between the metallic electrode and the solution when voltages above a critical value are applied; and, in combination with the thinness of the film, of holding a substantial charge at potentials below the breakdown voltage. This last characteristic brings the device into the category of a condenser. As a typical case; if an aluminum plate in an ammonium borate solution were formed to 30 volts the film is probably about 0.00001 mm thick and shows the very large capacitance of 0.2 μf per sq cm. Forming to a higher voltage of 350 volts increases the thickness of the film and reduces the capacitance to about 0.018 μf per sq cm of area. The use of this type of condenser is complicated with several special requirements. A polarizing direct voltage must be maintained on the condenser in the proper polarity at all times. There is a resulting leakage current flowing at all times. To this loss must be added the high loss in the electrolyte which results in a power factor ranging from 10 per cent up. The performance of these condensers is very sensitive to temperature, and the characteristics vary with temperature, frequency, forming voltage, polarizing voltage, operating voltage, and time. These facts coupled with the high loss make this condenser useful only in circuits where a large capacitance is needed, and this explains its appearance generally in filter circuits. A more convenient form of this condenser is the " dry " type in which the oxide film has been formed on one of two aluminum sheets and these sheets are separated by an electrolyte-saturated gauze.

7. CAPACITORS FOR SPECIAL USES

POWER-FACTOR CORRECTION. To be of use in power-factor correction a capacitor must possess two important qualifications. First, in order to compete with the synchronous condenser, it must have very low losses, for the losses of a synchronous condenser are only about 1 1/2 to 5 per cent of its kva rating. The static capacitor meets this requirement quite well by normally having losses amounting to about 0.25 per cent of its rating. When connected into a high-tension circuit by use of an auto-transformer the over-all power factor is between 1 and 1 1/2 per cent. Second, the static condenser must have a dielectric of very sure and quite high dielectric strength. There are several means of developing high dielectric strength, through the use generally of solid dielectric materials permeated with oil, special preparations, or inert gases. Oil replaces wax in the construction of condensers for high-voltage service for the combination of oil and paper is a much better conductor of heat than that of wax and paper. Mineral oil of about the same grade used in transformers is commonly used as an impregnating material. The several types of papers which have been used include Kraft, a combination of wood pulp and cotton and pure linen tissue.

There has been described * a new impregnating fluid for use in capacitors which is called Pyranol. This synthetic, non-inflammable, insulating liquid is used as a treating and filling material to replace waxes and mineral oils formerly used. It has a high dielectric constant and has chemical stability under high temperatures and electrical stress. Condensers impregnated with Pyranol are used in high-voltage surge generators and in general where great reliability at high voltage is required.

Illustrative of the capacitor using an inert gas as part of its dielectric is the " Permittor," † a commercial static capacitor used generally for power-factor correction. The Permittor makes use of nitrogen under pressure which serves as a cooling medium, and, in combination with a high-grade insulating paper, as the dielectric. The penetration of the gas into the paper results in a dielectric of high dielectric strength, low losses, and perfect chemical stability. The heat-transfer properties at the 225-lb-per-sq-in. pressure used are similar to those obtained with insulating oils. The condenser units are built up into rolls consisting of alternate layers of aluminum foil and layers of the high-grade tissue. The foils of opposite polarity protrude at opposite ends of the roll, and flanged disks of aluminum cover the ends, making good electrical and thermal contact. The rolls are assembled in a tank of pressed steel which serves as the chamber for the high-pressure nitrogen. The losses of this type of capacitor range between 0.2 and 0.4 per cent of the kva rating through the operating range of temperatures. This type of unit is built for voltages from 440 volts up to 33,000 volts.

COUPLING CONDENSERS TO HIGH-TENSION TRANSMISSION LINES. A very definite need exists for communication between the various parts of a power

* General Electric Co. † Products Protection Corp.

system. A means, immediately available, are the transmission lines themselves which link the various generating and distributing units together. Means must be had for this purpose, to connect to the power line without loss of power and without danger to the users of the communication system. The ideal linking unit is the capacitor with its high impedance to the power-frequency current and relatively low impedance to carrier-frequency currents. Another use that may be served through the power lines is through tapping the lines directly to secure a small amount of power for relay or signal operation. The capacitor coupling has also been used with synchronizing equipment, voltage indication, and metering.

The general form taken by the coupling capacitor is the condenser type bushing, originally developed as a means of surge protection for high-tension equipment. This type of bushing has inherent capacitance potentiometer characteristics and readily provides a source of low voltage. The insulator potentiometer has relatively high capacitance, and as it is constructed of concentric metal-foil cylinders about the high-voltage conductor, it forms an ideal capacitance potentiometer. The metal foil cylinders are the plates and the micarta is the dielectric of a series of condensers which can be considered as connected in series from the high-voltage conductor to ground. By adding a tap to the last step to ground a potentiometer is easily obtained.

INDUCTORS

An inductor is a device the primary purpose of which is to introduce inductance into an electric circuit. The term reactor is given to devices which introduce reactance into a circuit. There are numerous applications for such devices in electrical circuits, and the characteristics of these as used in power circuits are presented in this chapter. Current control is probably the most important function of an inductor, and this function is performed both continuously and intermittently. Among the applications are the following: short-circuit current limitation in power systems; surge and lightning protection in transmission lines; synchronous converter compounding; shunting of field windings, lamps, and other devices; ripple suppression in filters, welding equipment; current control through lamps, relays, motors, circuits; high-frequency oscillation suppression; parallel operation of unlike transformers; control of potential as in the auto-transformer; and numerous other circuit uses. The actual applications in the particular uses are presented in the appropriate sections of this volume.

8. AIR-CORE INDUCTOR

INDUCTANCE FORMULAS. The inductance of a conductor is a direct function of its dimensions and its arrangement, and for any given conductor the inductance may be increased by forming the conductor into a coil. With a given length of wire, wound with a given pitch, that single-layer coil has the greatest inductance, which has such a shape that the ratio $\frac{\text{diameter}}{\text{length}} = 2.46$ approximately. A measure of this increase of inductance for a given length of conductor may be had in the computation of the inductance of a conductor when straight and when formed to the optimum coil. An expression giving the approximate value of the inductance of a single-layer solenoid

(see Fig. 2) is $L = 0.03948a^2n^2K/b$ microhenrys, where n = number of turns of the winding, a = radius of the coil, measured from the axis to the center of any wire, b = length of the coil, and K is a function of $2a/b$, values of which have been calculated by Nagaoka. Dimensions a and b are expressed in centimeters. For a 10-turn winding of

No. 10 A. W. G. round copper wire formed into a compact coil of 2.46-in. diameter, and length of about 1 in., a calculation from the formula above gives an inductance value of 7.2 microhenrys. The inductor of this problem contains 77 in. of wire, and its inductance, when straight and distant from other conductors, is given by the expression $L = 0.002l\left(\log_e \frac{2l}{r} - \frac{3}{4}\right)$ microhenrys, where l = length of wire, r = radius of wire, measured in centimeters. A calculation from this expression for the straight wire inductance gives a value of about 2.85 microhenrys. The comparison of the two calculations shows an increase of over 2 1/2 times in the inductance value by the change from the straight wire to coil form.

Brooks has determined (*Bur. Standards J. Research*, Vol. 7, p. 289, August, 1931) that there is a most efficient multilayer coil form to produce the maximum inductance with a given length of conductor. This most efficient inductor was produced as a compact multilayer cylindrical coil with a mean diameter 2.95 times the side of the square cross-section. Other proportions varying somewhat from the optimum affect the inductance

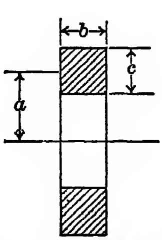

FIG. 1. Multiple Layer Inductor with Winding of Rectangular Cross-section

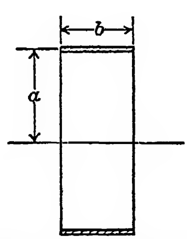

FIG. 2. Inductor with Single Layer Winding

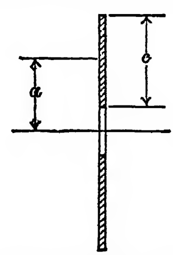

FIG. 3. Inductor with Spiral Winding

only slightly. When the ratio of mean diameter to side of square cross-section is 2.80, the resulting inductance is only 0.04 per cent less than the maximum value. It is generally convenient and within limits of accuracy to consider the optimum form as having the dimensions $2a = 3b$ with $b = c$ (see Fig. 1). For the optimum form of multilayer coil the accurate expression of inductance has been modified, giving the expression $L = 0.04274an^2$ microhenrys where a is measured in inches and n = the number of turns. This formula presupposes a uniform current distribution over the square cross-section of the coil.

Some general simplified formulas for the inductance calculation of air-core inductors have been given by Wheeler (*Proc. I.R.E.*, Vol. 16, p. 1398, October, 1928) and apply to the multilayer (Fig. 1) single-layer helical (Fig. 2), and single-layer spiral coil (Fig. 3).

The expression for the inductance of the multilayer winding

$$L = \frac{0.8a^2n^2}{6a + 9b + 10c} \text{ microhenrys} \tag{1}$$

is accurate to ± 1 per cent when the terms in the denominator are about equal. All dimensions are inches. The single-layer helical winding (Fig. 2) has an inductance expressed as

$$L = \frac{a^2 n^2}{9a + 10b} \text{ microhenrys} \tag{2}$$

which is accurate within ± 1 per cent when $b > 0.8a$. The inductance of the single-layer spiral coil (Fig. 3) is given in the expression

$$L = \frac{a^2 n^2}{8a + 11c} \text{ microhenrys} \tag{3}$$

or in terms of Fig. 2

$$L = \frac{a^2 n^2}{8a + 11b} \tag{4}$$

This expression is accurate to ± 5 per cent when $c > 0.2a$ (Fig. 3), or $2a > b > 0.2a$ (Fig. 2). In general form eq. 2 should be used for helical coils, whenever $b > a$. For short helical coils eq. 4 is more accurate, particularly when $a > b > 0.2a$. The accuracy of these expressions may be less than stated for coils of very few turns or when skin effect or distributed capacitance is appreciable.

If the coil is mounted on a toroidal form instead of a tubular cylinder, its inductance in microhenrys is

$$L = 0.01257n^2 (R - \sqrt{R^2 - a^2}) \tag{5}$$

in which R = distance from the axis to the center of the winding cross-section, a = radius of each turn of the winding, and n = number of such turns (all dimensions in cms). Using the 77 in. of conductor formed into a toroid an inductance of several microhenrys could be designed.

CONSTRUCTION. The turns of an inductor winding generally must be supported, and where no magnetic core is used, the coil is formed on a frame of wood, composition, concrete, or some other good insulator. If the winding has sufficient stiffness to hold its form it may have no support but rest entirely on the terminal connections. Provision must be made in the construction of an inductor for the electrical insulation of closely adjacent turns, the liberation of the energy generated in the winding, and the strengthening against interwinding stresses. This last factor is important to the construction of series reactors built for short-circuit protection in electric generating systems.

ENERGY DISSIPATION. The losses in the inductor are due to the heat energy liberated in the wire following the flow of current. A measure of this loss is had from the expression for the power which is $P = I^2 r$, in which P the power in watts, I the effective current in amperes, and r the resistance of the winding. The liberated heat energy may be carried away by fluid convection through the winding or by the supporting frame. Construction according to accepted practice will limit the temperature rise of the windings to values specified in the standards of the A.I.E.E. Normal operation will require that the insulation between turns withstand certain potentials. Generally, insulation will be of such a character that it will withstand potentials in excess of normal operation, but occasional abnormal conditions place very high stress on the insulation. Such conditions arise when an attempt is made to open an inductive circuit. As the circuit switch is opened the current must decrease from its steady value to zero. As the current diminishes rapidly, the voltage of self-induction is very high, and maintains an arc at the switch contacts until the energy of the magnetic field is dissipated. The energy stored in the field is $LI^2/2$ joules, with L in henrys and I effective amperes of current. In circuits of high inductance value, provision is generally made to dissipate this energy safely in a discharge resistance which is connected temporarily into the circuit as the switch is opened.

DISTRIBUTED CAPACITANCE. Since the adjacent turns of the winding on an inductor are at a difference of potential, and electrically insulated, they constitute the elements of a capacitor. The capacitance between any turn to the others of a winding affects the inductance action of the device, particularly at high frequencies. The effect is not of great importance in power applications, except when an inductor is being used to suppress a high-frequency oscillation. In this use the distributed capacitance would by-pass the high-frequency currents and nullify the choking action of the inductor.

9. INDUCTOR WITH FERROUS CORE

INDUCTANCE FORMULA. The use of a ferrous core to form a complete magnetic path for the flux increases the amount of magnetic flux set up and so increases the induc-

tance of the winding many times. The inductance of an iron torus with a closely spaced winding is

$$L = 0.4\pi n^2 \frac{\mu A}{l} \text{ microhenrys}$$

where n is the number of turns of the winding, A the cross-section of the winding, l the mean length of the winding (dimensions in centimeters), and μ the average permeability for the conditions of use (see Section 2, Magnetic Materials, for a discussion of the proper value of permeability to use). This is a fundamental equation for any magnetic circuit and has a very general use in magnetic calculations. The expression may be written

$$L = 0.4\pi n^2 P$$

where P = the permeance of the magnetic circuit computed from the dimensions of μ, A, and l. The permeance of a magnetic circuit may be represented as $1/\mathcal{R}$, where $\mathcal{R}$ = the total reluctance of the circuit. This reluctance is composed of the reluctances of all the parts of the magnetic circuit and may include different kinds of iron, as well as air or other non-magnetic material.

LOSSES. The use of an iron or ferrous alloy core for an inductor usually increases the losses of the inductor. These losses occur from two causes, hysteresis and eddy currents. A complete discussion of them and the method of calculating their magnitude is contained in Section 2, Magnetic Materials.

EQUIVALENT SERIES RESISTANCE. Since the core of an inductor is an integral part of the device, energy losses which occur in this material are considered as energy losses of the inductor. The losses in the ferrous core must therefore be added to the loss due to the current flow in the inductor winding. This gives a total loss

$$W_{\text{total}} = W_e + W_h + I^2 r$$

where I is the effective current flowing through the winding with an ohmic resistance r under a given set of conditions. The total loss may be set equal to a quantity ($I^2 r_{\text{equiv}}$), where r_{equiv} is the equivalent series resistance of the inductor. From its origin, it can be seen that r_{equiv} does not have a single constant value for a given inductor but will vary with the magnitude and frequency of the current through the winding as well as with the temperature of the device. Methods for the measurement of the losses, effective inductance, and other characteristics of reactors are presented in Section 5, Measurements and Measuring Apparatus.

CURRENT WAVE FORM. In an iron-cored inductor upon which is impressed a sinusoidal emf the flow of current is very complex and usually not of sine-wave form because of the variation of permeability during the current cycle. Neglecting the small resistance reaction, the emf of self-induction must be a sinusoidal voltage equal and contrary to the impressed voltage. This requires a sinusoidal time variation of flux, and this flux must be produced in the iron core by the current in the winding. For a core material being worked through a certain hysteresis loop the resulting current flow can be predicted as shown in Fig. 4. If the hysteresis loop carries into the saturation region the current rises to very high peaks to produce the necessary flux changes.

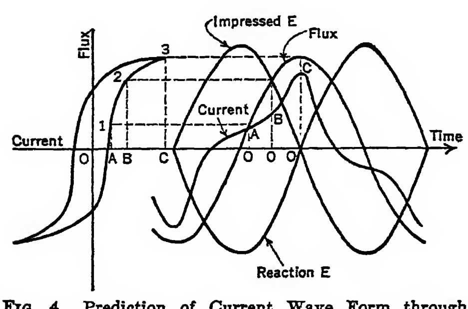

FIG. 4. Prediction of Current Wave Form through Hypothetical Inductor on which Sinusoidal emf is Applied

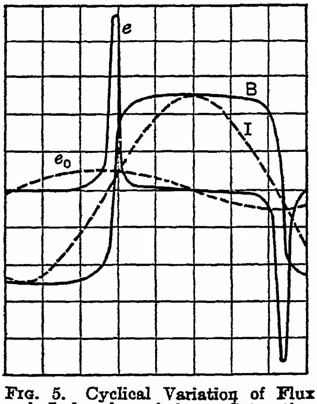

FIG. 5. Cyclical Variation of Flux and Induced emf in a Saturating Reactor through which a Sinusoidal Current is Flowing

If the iron-core inductor is only one of a series of circuit elements, it may be that a sinusoidal alternating current will be flowing through the circuit. It has been shown that under these circumstances the voltage across the inductor may reach very high peak values. The curves of Fig. 5 show the cyclical variations of a saturating reactor, through which a sinusoidal current is flowing. In the curves of Fig. 5 are shown the wave of magnetic flux, of the induced voltage e, the sine wave of current, and the voltage e_0 which would be induced if the flux density B were a sine wave of the same maximum value. The variation of the induced voltage e approximately represents the cyclical variation of the instantaneous inductance. It is apparent from the curves of Figs. 4 and 5 and from preceding paragraphs that the voltages, currents, inductance, and resistance which may describe the actions of an inductor are far from sinusoidal or constant quantities. Therefore measurements on devices of this type are generally interpreted in terms of equivalent or effective values.

TIME CONSTANT. In many circuits involving the use of an inductor there are periodic changes in the flow of direct current. It is sometimes required that the inductor control the rate of change of current in such a circuit. The growth of current in an inductor of constant inductance L is expressed as

$$i = \frac{E}{r}(1 - \epsilon^{-rt/L})$$

where i = current at any time t seconds after the circuit is closed; E = constant impressed voltage; r = resistance of the winding; ϵ = Napierian logarithmic base 2.7183. The curve of Fig. 6 shows the current rise in an air-core inductor and follows very closely the equation above. However, with the iron-core inductor the inductance is not constant

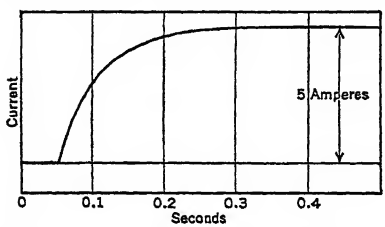

FIG. 6. Current Rise in an Air Core Inductor, L = 0.62 henry, r = 13.2 ohms (After Morecroft)

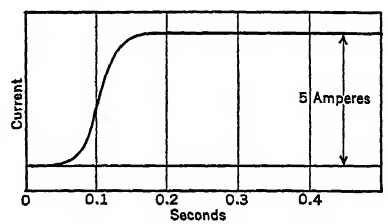

FIG. 7. Current Rise in Saturating Reactor, L variable, r = 18.7 ohms (After Morecroft)

and varies with increase of current. This effect is seen in the curve of Fig. 7, the form being very unlike that of Fig. 6. These effects must be considered when it is required that the inductor control the current growth. The magnitude of the exponent in the expression above determines the rate of current rise in the inductor. For this reason the quantity L/r is a characteristic constant (when L and r are constant) of the inductor and is given the name "time constant." If the numerical value of L/r, in seconds, is substituted in the above equation it is seen that it is the time taken for the current to reach 63.2 per cent of its final value. The time constant is generally used in the comparison of inductors and, from its dimensions, indicates the effectiveness of a given winding in producing inductance for a given resistance.

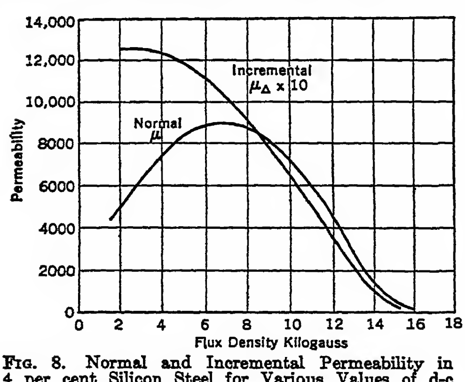

FIG. 8. Normal and Incremental Permeability in 4 per cent Silicon Steel for Various Values of d-c Saturation (C. R. Hanna, *Trans. A.I.E.E.*)

ACTION OF D-C MMF WITH A-C MMF. Many applications of inductors require their use in circuits carrying both direct and alternating currents of more than one frequency. Both these situations result in unusual effects on the inductance of the device. Since some of the effects avail themselves for application in certain control circuits, it is common for

an inductor, in this work, to have two windings, one carrying the circuit alternating current and the other carrying a direct current. The effective inductance offered to the alternating current depends upon the magnitude of both the direct current and the alternating current. The state of magnetic saturation due to d-c mmf depends upon the magnitude and direction of the direct current. For any particular direct current

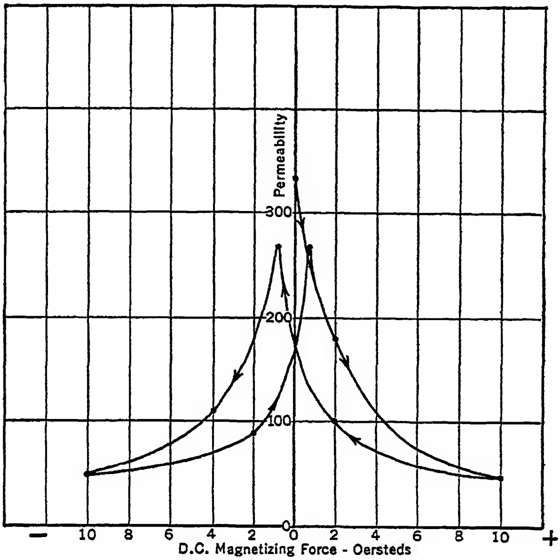

FIG. 9. Butterfly Curve. Variation of incremental permeability to a small a-c mmf for various d-c mmfs acting on a medium silicon steel core

the iron core is brought to some operating point on the hysteresis loop. When an alternating current superimposes its mmf upon this as an origin, a small hysteresis loop is executed. It is the average slope and the area of this small displaced hysteresis loop which give a measure of the permeability and losses of the iron under these conditions; and these determine the effective inductance and resistance of the inductor for that particular alternating current. The permeability determined from the displaced hysteresis loop is termed the "incremental" permeability (see Section 2, Magnetic Materials). Generally the mmf due to the direct current decreases the permeability for the alternating current with the exception of the case of low d-c magnetizing forces acting in conjunction with residual flux from some previous magnetization. The curve of Fig. 8 shows the variation of incremental permeability for various values of d-c saturation in a 4 per cent silicon steel.

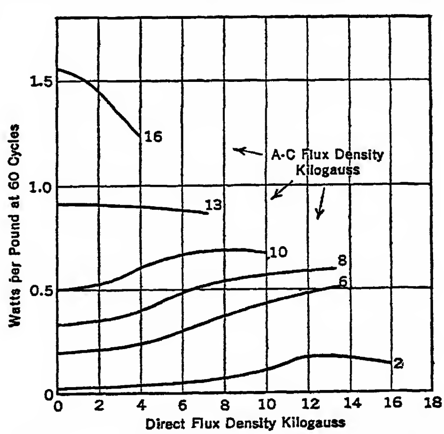

FIG. 10. Variation of Hysteresis Loss in 4 per cent Silicon Steel for Various Conditions of a-c and d-c Flux Density (Edgar, *Elec. Eng.*)

When the d-c magnetization in a core is varied with increasing values first in one direction and then the opposite, the effect on the a-c permeability is as shown in Fig. 9. In this "butterfly" curve it is seen that, under certain conditions, the impressed direct mmf increases the a-c permeability.

Both of the energy losses in iron due to hysteresis and the flow of eddy currents are

affected by the combined a-c and d-c saturation. Edgar (*Elec. Eng.*, Vol. 53, No. 9, p. 318, February, 1934) has determined that, in the range of alternating flux density below a critical value, hysteresis loss tends first to rise, reaches a maximum, and then decreases as the d-c magnetization is superimposed upon a fixed a-c flux component. It has been found that the critical value of the alternating flux density for silicon steel lies in the range of 13,200 to 13,800 gausses. The curves of Fig. 10 show the variation of hysteresis loss with direct flux density for various values of a-c flux density. Sidhu (*Elec. Eng.*, Vol. 52, No. 9, p. 625, September, 1933) has developed expressions for the hysteresis loss in materials carried through displaced or unsymmetrical hysteresis loops. These expressions are of the general type of the Steinmetz formula, but for high magnetizations an expression of another form more accurately expresses the loss, and each case requires particular value of coefficients and exponents. Spooner has shown that, for a given B increment, the hysteresis loss increases with the displacement from the normal position. The ratio of the loss of the displaced loop to that of the normal loop is termed the displacement factor. Under certain conditions this displacement factor may amount to 10 or more.

When alternating currents of more than one frequency impress their mmf on the core of an inductor a very complicated effect results. This may be summarized in two parts: (1) the effective inductance to each frequency is altered by the presence of the other current; (2) the inductance offered to each frequency varies cyclically at the frequency of the other component.

EFFECT OF AIR GAP. When it is essential that an iron-core inductor have a more constant inductance, minimizing the effects of d-c saturation and high a-c mmf's,

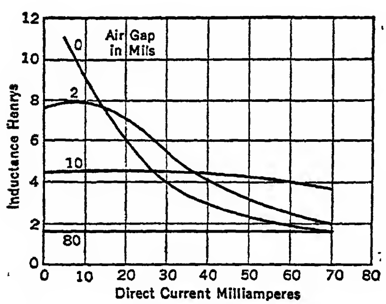

FIG. 11. Variation of Effective a-c Inductance with d-c Magnetization for Various Gaps. Alternating current of 1.0 milliampere (Turner, *Proc. I.R.E.*)

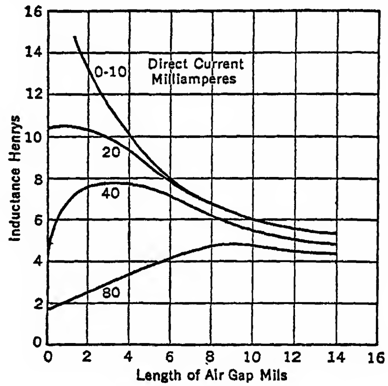

FIG. 12. Variation of Effective a-c Inductance with Air Gap for Various d-c Magnetizations. Alternating current of 10.0 milliamperes (Turner, *Proc. I.R.E.*)

an air gap is left in the magnetic circuit. This causes a reduction of the amount of self-induction possible with a given winding. The amount of decrease depends upon the comparative lengths of iron and air in the magnetic circuit and upon the degree of saturation of the iron. Hanna (*Trans. A.I.E.E.*, Vol. 46, p. 155, 1927), has shown a method for the design of reactances and transformers which carry direct current, including a determination of the best value of air gap. H. M. Turner (*Proc. I.R.E.*, Vol. 17, p. 1822, October, 1929) has experimentally shown the effect of initial magnetic state, air gap, and superposed direct currents on the inductance to alternating current of an inductor. The curves of Figs. 11 and 12 show the results of measurements made on an inductor with a winding consisting of 2500 turns of No. 36 A. W. G. wire. This winding served as a path for both the d-c and a-c currents. The core consisted of two L-sections each having 44 laminations, 14 mils in thickness, of 3.5 per cent silicon steel. The dimensions of the magnetic circuit were: length 16.3 cm, cross-section 2.82 sq cm, and volume 46.2 cc.

The curves of Fig. 11 show the characteristic decrease of effective inductance with d-c magnetization, with the slight initial increase due to remnant magnetization. For large air gaps and with no iron core, the inductor has very little change in inductance indicating the action of an air-core inductor.

The curves of Fig. 12 show that under certain conditions the inductance of the inductor is increased by an increase of air gap. This is due to the action of the air gap in lowering

the degree of saturation brought about by the direct current. Increasing the air gap corresponds to diminishing the ampere-turns per centimeter of iron of the d-c magnetizing force, and it is this which causes the rise in effective inductance for the curves of Fig. 12.

A very large number of magnetic circuits for inductors are made up in the manner of the inductor for which curves are given above. To complete the magnetic circuit, which is usually in two sections, these are brought together forming butt or lap joints. At these butt joints the air gap is introduced, using spacers of paper or fiber. Owing to the irregularities of the ends of the laminations it is difficult to secure an accurately measured, uniform air gap, and with no spacers in the joint there is still a considerable effective gap. The effective value of air gap may be more or less than the measured gap not only because of irregularity of the laminations, but also on account of fringing of the flux at the gap. Since the effective inductance is inversely proportional to the reluctance of the magnetic path, the results of Fig. 11 may be used to determine an incremental reluctance of the magnetic circuit. For low saturations this reluctance is practically all due to the air gap.

PRACTICAL DESIGN CONSIDERATIONS. The usual commercial reactor is built up with a laminated silicon steel core, an air gap, usually adjustable, and a winding of turns sufficient to give the desired inductance. In such reactors the air gap is commonly of such length as to constitute the major reluctance of the magnetic circuit. The reluctance of the iron portion of the magnetic circuit may then be neglected, provided the flux density in the iron is not exceeding about 80,000 lines per square inch. Under such conditions, the expression for inductance given earlier in this article becomes

$$L = \frac{3.2n^2 A}{10^8 l} \text{ henrys,}$$

where n = number of turns in coil; A = cross section of path in gap, square inches; l = length of gap, inches. To check that the flux density is not excessive it should be calculated from

$$B_m = \frac{3.2\sqrt{2}\, nI}{l}$$

where I = effective value of current, amperes; B_m = maximum value of flux density.

The iron-core reactor is generally built up using a magnetic circuit of either the toroidal or the E form. These are analogous to the core type and shell type of cores which are used for the magnetic circuits of transformers. Economy is effected by separate assembling of winding and core, and this is possible when the core is made up of laminations. These are punched in such form that the winding may slip over part of the core (middle leg of the E), after which the magnetic circuit is completed by an additional stack of laminations. The windings are constructed with insulated copper wire, the insulation being enamel, cotton covering, silk covering, or a combination of these. Adjacent layers are separated by one or more layers of paper, cloth, or cambric, and the whole winding is supported on a paper form or spool.

The design of reactors follows very closely those principles laid down in the design of the modern commercial power transformer, and reference may be made to any good source on transformer design (see Section 10). In a power transformer the core losses are essentially constant, and copper loss varies according to the conditions of loading. Reactors, however, are submitted to widely varying conditions, and the energy dissipation due to core and winding loss will vary in a wide range of values. Thus the reactor surface which must be allowed for radiating the dissipated energy will vary between wide limits. An allowance of anywhere from 1 to 6 sq in. of radiating surface per watt loss will usually not cause a temperature rise exceeding 55 deg cent, but this of course depends upon the cooling conditions. Experience has shown that, for a reactor of ordinary dimensions, continuous operation will be possible if there is a radiating surface of 2 sq in. per watt of power. Safe current ratings for a reactor winding vary widely, and any rating will depend upon the total reactor losses, not only on the copper loss. Considering this we find that current ratings may vary from 500 to 2000 amp per sq in.

Costs of reactors will vary widely depending upon the design, number of windings, materials, and conditions of use. An average figure for the cost of small reactors would be $5.00 per kva of rating.

10. ADJUSTABLE INDUCTORS, VARIOMETERS

From the characteristics of inductors operating under the various conditions detailed in this chapter, it is seen that inductance may be adjusted by one of several means. For a given inductor it is possible to vary the number of effective turns in the winding, and this is frequently done by arranging a sliding contact on the winding or on tap points to the

winding. When the full potential is impressed across the whole winding the sliding contact permits of a potentiometer use for the adjustable supply of voltage. This is the essential feature of an auto-transformer, or a starting compensator. The influence of an air gap on the inductance of an inductor was seen, and this effect is used for adjustment. Adjustment is effected by the control of a butt-joint air gap or through the motion of a wedge which can be moved in and out of a wedge-shaped cut in the magnetic circuit. The adjustment of a-c inductance by variation of the d-c saturation is probably the most widespread method of control, and accomplishes the desired end without moving parts and with small energy expenditure.

A very convenient continuously variable inductor is formed of two windings, generally in series and mounted so that one can rotate within the other. Although the self-inductance of the two coils is constant, the total inductance of the combination changes with the change of the mutual induction between the two coils. The inductance of this device is

$$L_{\text{total}} = L_1 + L_2 \pm 2M$$

where L_1 and L_2 are the individual self-inductances and M = the mutual induction. Another variometer effects the inductance adjustment by means of a variation of the overlap between adjacent flat coils. In variometers of these two types it is possible to adjust the inductance in a range of values of about 10 to 1. Adjustable inductors of the several forms have wide use in laboratories, and the principle of this device is applied in the development of the induction-type feeder voltage regulator.

11. CURRENT LIMITING REACTORS FOR POWER SYSTEMS

Reactors for short-circuit current limitation in power systems are generally installed at one or more of the following locations in a system: (1) generator reactors on the leads of generators feeding bus-bars; (2) bus tie reactors on the bus-bars between different bus sections; (3) feeder reactors on feeder circuits fed from bus-bars to protect switching equipment. The prevention of heavy currents on short circuits avoids severe mechanical stresses in connected apparatus. The placing of reactors in feeder circuits prevents a serious voltage drop in feeders other than the one in which the short circuit occurs, and reduces the probability of apparatus falling out of step.

SPECIAL DESIGN REQUIREMENTS. Inductors designed for use as short-circuit reactors must meet certain special requirements, and in consideration of these, the turns of the inductor cannot be wound in the close arrangement which would produce the largest inductance value. H. B. Brooks has noted (*Bur. Standards J. Research*, Vol. 7, p. 289, August, 1931) the important considerations to be: (*a*) ability to withstand heating caused by heavy overloads; (*b*) ability to withstand destructive forces during short circuits; (*c*) high flashover voltage; (*d*) low skin-effect resistance ratio. To minimize the effects of the heating and interwinding forces (both of which are proportional to the square of the current), layers and adjacent turns are well spaced. To give the winding mechanical strength the turns and layers are spaced apart and held by strong cleats of heat-resisting insulator material, or they may have concrete supports cast around them. During short-circuit conditions, the normally low turn-to-turn voltage is increased many fold and the spacing of turns must be such as to prevent flashover. To aid flashover prevention and to provide protection against short-circuited turns, the cable winding is insulated with a material having a high dielectric strength and impregnated with compounds which render it heat and fire resisting. For higher line voltage, fewer turns are placed in the end layers to reduce the stress on the insulation. It is important that copper loss in the winding be minimized during normal operation. This is effected by stranding the conductor, the individual wires of which are enameled and insulated one from another.

CONSTRUCTION AND PERFORMANCE. Short-circuit reactors are built for outdoor or indoor service and are designed for either air cooling (dry-type) or for cooling by oil immersion (wet-type). The application and development of large current-limiting reactors have occurred mainly in the forms using no core material chiefly from reasons of economy. Reactor windings are generally formed into parallel multilayer spiral disks. These windings are symmetrically spaced and wound so that the total current will be equally divided and circulating current will be prevented.

For a given operating frequency the reactor will possess a reactance $X = 2\pi fL$. From this value the "per cent reactance" of the reactor may be calculated as $\frac{(100\,IX)}{V}$, where I is the normal full-load current through the reactor and V the normal voltage across the circuit in which the reactor is placed. As the normal voltage drop through the reactor is equal to IX, the per cent reactance is actually the per cent ratio of this voltage drop to

the circuit voltage in which it is used. When the reactor winding is inserted in one branch of a Y, the voltage, V, is volts to neutral.

The standards of the A.I.E.E. specify normal performance and tests for current-limiting reactors. According to the standard, the rating of current-limiting reactors shall be expressed in kilovolt-amperes, absorbed at the rated current and frequency on a circuit of specified voltage rating. Since the resistance of the reactor is usually negligible compared with the reactance, the kva rating may be determined as I^2X, and the value of reactance may be used as the impedance of the reactor. The standard further requires that " current limiting reactors having an impedance of 3 per cent or more shall be capable of withstanding without injury for five seconds the maximum current that would result from any short circuit on the system with normal line voltage maintained at the supply terminals and with only the inherent impedance of the reactors in the circuit. Reactors having an impedance of less than 3 per cent shall be capable of withstanding without injury for five seconds a current equal to 33 1/3 times the rated current."

TEMPERATURE RISE, LOSSES. For the purposes of standardization the temperature of the copper under short-circuit conditions given above shall not exceed 250 deg cent for class A insulation, or 350 deg cent for class B insulation where calculated by the formula given below, assuming: (*a*) that all the heat is stored in the copper, and (*b*) an initial temperature of 105 deg cent for class A insulation and 125 deg cent for class B insulation.

The formula for the increase in temperature during short-circuit conditions is:

$$\theta = At\left[\frac{B}{2\theta_1} + \frac{618.4E}{B}\right] + \theta_0$$

where θ = final temperature, degrees centigrade; θ_0 = initial temperature, degree centigrade; θ_1 = absolute initial temperature = $(\theta_0 + 234.5)$; t = time, seconds; E = ratio of eddy current to I^2R loss at 75 deg cent; $A = \dfrac{\text{watts per pound (at } \theta_0)}{180}$; $B = 2\theta_1 + At$.

" The losses to be considered in current-limiting reactors shall be the load losses. These losses consist of I^2R losses in the winding due to load current, and stray losses due to stray fluxes in the windings and other metallic parts. The stray load losses shall not include the losses produced by the field of the reactor in adjacent apparatus or materials." Actually, when reactors are installed at a distance less than half their diameter from any metallic structure, appreciable eddy current and hysteresis losses will be produced in such structure. Thus in the oil-immersed reactor there is considerable energy loss in the laminated iron strips, used to shield the oil tank walls, and this increases the effective resistance of the reactor.

RATINGS. Current-limiting reactors are constructed in a wide range of sizes running up to normal current ratings of 7500 amp. Reactors are generally limited to use in circuits of 13 kv or less, but reactors for grounding neutrals of 220,000-volt transformer banks have been constructed. For generator, bus, and feeder installation, reactors are constructed with a per cent reactance up to 5 per cent. Typical of the service for large generator and bus tie circuits one manufacturer * supplies a reactor rated at 11 kv, 3750 amp, 2850 kva, 25 cycles. The guaranteed efficiency of reactors of this type is given as 99.56 per cent. The costs of current-limiting reactors vary over a wide range. As a general statement, based on a copper cost of 10 cents, the cost per kva may run as low as 65 cents on very large reactors, and it may run as high as $16 per kva for small reactors.

MAGNETS, MAGNETIC DEVICES

Magnets and magnetic devices function through the use of magnetic flux. This flux may be intermittently generated by means of a coil carrying electric current, or it may be residual in a body of iron. This permits the grouping of magnetic devices broadly into two classes, those employing electromagnets and those employing permanent magnets.

Magnetic devices are very widely used in all electrical circuits and serve many utilitarian purposes. In the electric power service, circuit breakers, switches, and overload relays find extensive application. Among the many industrial and commercial uses there are ore separation, lifting and holding magnets, valve operation. Magnets are an indispensable component of electrical motors and generators as well as of electrical meters and relays. The control and interconnection of communication circuits is effected by magnetic relays.

Magnetic devices generally are made up with some type of ferrous alloy core. The chemical constitution and the physical and thermal treatment vary according to the requirements producing a magnetically "hard" or "soft" material. The iron used in the structure not only increases the flux above the value which could be set up in air, but directs it to the point of application. The relative value of materials as to the setting up of flux is represented by the permeability of the material, and generally it is desired that the material have a reasonably high permeability and, in the case of permanent magnets, a high retentivity (see Section 2, Magnetic Materials).

12. PERMANENT MAGNETS

A "permanent" magnet to be considered such must retain the major portion of its magnetism after being subjected to moderate demagnetizing forces. It usually is not of much value as a magnet unless it can produce a magnetic field of fairly high intensity.

When a piece of steel has been magnetized it will contain magnetic flux to a certain extent throughout its mass. The term "remanence" is used to designate the magnetic induction at the magnetic equator of a permanent magnet with no external magnetizing or demagnetizing force. Most important in the design of permanent magnets is the deter-

mination of the relation between the remanence of a magnet and the various factors which determine its value. These factors include the magnetic properties of the steel and the shape and dimensions of the magnet. Of particular interest to the manufacturer are the problems involved in chemical composition, melting and rolling practice, hot forming, and annealing and hardening treatments. The last group bears an important relation to the physical characteristics of the product as well.

GENERAL DESIGN FACTORS, EFFECT OF AIR GAP. The type of steel to be used in a permanent magnet is determined by the permissible size of the magnet, the magnetic properties of the steel, and the cost of the steel. Cheaper steels of comparatively low coercive force may be used for some magnets in which size and weight are not important. It is often possible to compensate for a lower coercive force by increasing the length of the magnet, since the ability of a magnet of given retentivity to hold its magnetism is proportional to its length. The magnetic flux density in a bar magnet is usually lower than the remanence of the steel because the ends of the magnet exert a demagnetizing force on the rest of the bar. This effect is greater in bars whose ratio of length to cross-section is small, and is negligible in very long thin magnets.

A knowledge of the coercive force of the material is of value when estimating the relative magnetic strengths of short magnets of the same size but of different materials. If the coercive force is very high, as it is in cobalt magnet steel, short magnets may be made which will have as high magnetic strength as considerably longer magnets made of material whose coercive force is lower. However, the relative strength of long thin magnets is dependent primarily on the residual induction of the material used. Long, slender magnets are capable of greater magnetic strength if made of tungsten steel than if made of any other common steel, because the residual induction of tungsten steel is relatively high.

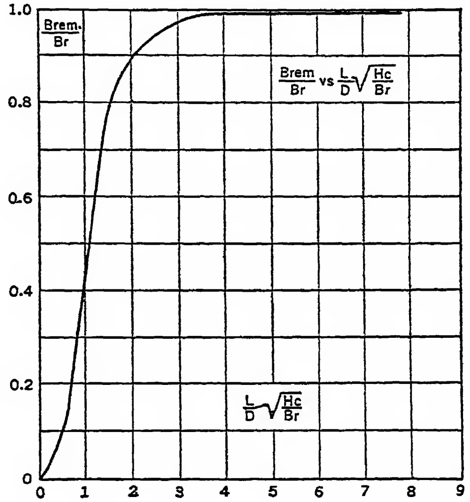

FIG. 1. Curve of Generalized Expression for Permanent Magnets, Relating Remanence and Physical and Magnetic Dimensions (Scott, *Trans. A.I.E.E.*)

THE DESIGN OF PERMANENT MAGNETS. Extensive investigations have determined a relation between the remanence of any permanent magnet and the parameters of physical dimensions and the axial intercepts of the demagnetization curve. This generalized relation is shown in the curve of Fig. 1 below and holds for bars of widely different compositions, magnetic properties, dimensions, and heat treatment.

In this curve the quantities related are:

B_{rem} = remanence, the magnetic induction at the magnetic equator of a permanent magnet with no external magnetizing or demagnetizing force. Values of B_{rem} given are without pole pieces on the magnets, in gausses.

B_r = residual induction, the magnetic induction in a ring or infinitely long straight bar after the value of H has been reduced from H_{max} to 0. The value of B at the intersection of the hysteresis loop with the B axis, in gausses.

L = the actual developed length of a magnet.

D = the equivalent diameter of a magnet $= 2\sqrt{\frac{\text{section area}}{\pi}}$

H_c = coercive force, the value of H required to reduce B from B_r to 0 in a ring or infinitely long bar. The value of H at the intersection of the hysteresis loop with the H axis, in oersteds.

L/D = the dimension ratio of a permanent magnet.

The form of this relation indicates that, with other factors constant, the remanence of a magnet is roughly proportional to $\sqrt{B_r}$, and for large values of dimension ratio or coercive force is practically equal to B_r.

Although the results given in Fig. 1 were derived from data on bar magnets, the general conclusions drawn are applicable to magnets of any shape if L is assumed to stand for the effective length of the magnet. By effective length is meant the length of a straight bar magnet of equal cross-section and magnetic properties, having the same remanence as the given magnet.

CRITERIA OF MAGNET QUALITY. A number of quantities have been used as criteria of the magnetic quality of magnet steel. The quantity $(BH)_{max}$ has been demonstrated as a measure of the maximum amount of external energy which can be supported per unit volume of a given magnet steel, and that this in turn defines the term "magnetic quality" of a magnet steel.

An experimental verification has been made of this criterion, and a relation between $(BH)_{max}$ and (B_rH_c) has been given to facilitate the determination of "magnetic quality." The curves of Fig. 2 above give a graphical comparison of the demagnetization curves and (BH) curves for various kinds of magnet steel.

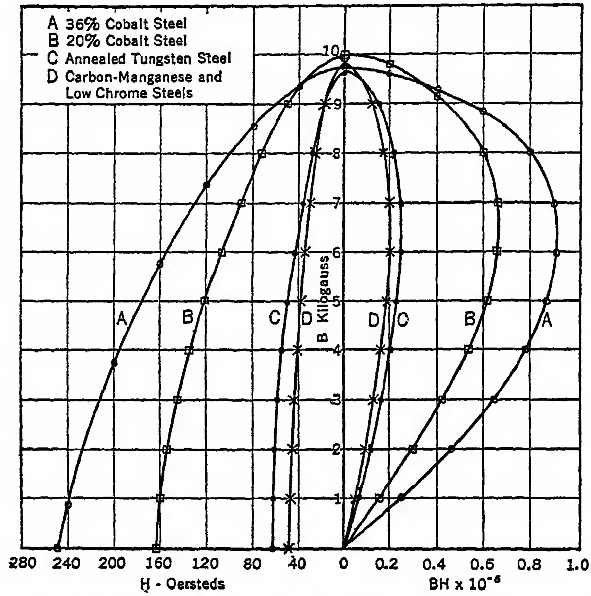

FIG. 2. Typical Demagnetization Curves and Curves of BH vs. B for Various Kinds of Magnet Steels

MAGNETIZATION, CONSERVATION. To obtain the theoretically maximum strength, magnets should be magnetized with a force sufficient to magnetize the steel completely. Practically, it has been found that satisfactory results are obtained with common magnet steels when they are magnetized with a force approximately five times the value of the coercive force of the steel. Well-designed commercial magnets have values of flux density in the middle region at about two-thirds the residual induction of the steel. The magnetizing force may be applied to a material by placing it in the magnetic field inside a solenoidal winding which is carrying a large direct current. A very large current acting for a short duration will be effective, this current being gradually reduced to a small value. If more convenient the magnet may be applied to the poles of a strong electromagnet. If possible the magnet should be magnetized in its final condition, with pole pieces attached. If magnetization is effected on the poles of an electromagnet, and the magnet is then withdrawn and pole pieces applied, the residual magnetism will be less than if the magnet has the pole piece attached when the magnetizing force is applied. It is therefore of importance that soft-iron pole pieces be constantly across the poles when they are magnetized and until the magnet is installed in the apparatus.

13. ELECTROMAGNET WINDINGS

The electromagnet is usually composed of a winding and an iron-air magnetic circuit more or less permanently related to the winding. The winding, when carrying an electric current, sets up a magnetic field which is a direct function of the number of turns and the current flow. To localize the magnetic field and to intensify it, a core or shell, or both, of magnetic material are added to the winding. When the core is fixed within a solenoidal winding, a bar electromagnet results. If the core is movable the electromagnet is of the plunger variety.

The function of the electromagnet is to provide a magnetic field in space. This magnetic field may be used in the operation of electrical rotating machinery, or may serve to magnetize materials under chemical or physical research. In addition to these fundamental uses there is the action used in almost an infinite number of devices—that of the attraction of magnetic objects in a magnetic field.

In switches, relays, and kindred magnetic devices the iron attracted in the magnetic field is usually in the form of an armature or clapper linked or hinged to the shell or core of the structure. The attracted magnetic material may also be in the form of a free body such as the material lifted by an ore separator or lifting magnet.

CORE MATERIAL IN ELECTROMAGNETS—MAGNETIC CHARACTERISTICS. The magnetic characteristics of the iron used in the core and shells of electromagnets will be considerably different from those desired in permanent magnets. An electromagnet is generally intended for intermittent use, that is, magnetizing current is applied when it is desired that the magnet act. When it is desired that the electromagnet cease to act, the magnetizing current is disconnected. Ideally, then, when the current is reduced to zero, it is desired that the attractive force of the electromagnet immediately cease and become zero. This would require the material being acted on by the magnetizing force to have zero residual induction and zero coercive force. An attempt to secure this ideal condition is made by the manufacture and use of magnetically soft materials such as carbon-free iron, low-carbon silicon steel, and the soft alloys of iron.

Beyond the magnetic requirements of low coercive force and residual induction it is generally desired that the core and shell material have the possibility of a high maximum induction. This requires the use of material with reasonably high magnetic permeability. In certain relays used in communication circuits special iron alloys with nickel and cobalt are useful in setting up high flux densities. Such use is of particular importance in telephone exchanges where space is at a premium and devices must be small. To set up the necessary action forces in small relays requires high flux densities, and to do this with material of small section requires material capable of high flux densities.

FUNDAMENTAL ACTION IN ELECTROMAGNETS. The fundamental law underlying the motion of a magnetic body in a magnetic field is that the free body always is forced to move in a direction such as to decrease the total reluctance of the magnetic circuit. For a given change in reluctance the force causing this motion is proportional to the square of the number of lines of magnetic flux threading through the body. It is obvious from these facts that a large amount of flux is desirable to secure sizable forces, and this flux should be concentrated in small localities so that it may act on small magnetic bodies. This desirable result is most difficult of achievement. When an iron torus is wound with a uniform winding through which current is passed, practically all the magnetic flux set up by the winding is contained in the iron. To expose some object to the flux requires the introduction of an air gap in such a toroid. With even very small air gaps the magnetic flux in the iron ring does not pass directly from one face of the gap to the other. There is fringing of the flux around the gap which, in large gaps, appreciably diminishes the amount and concentration of flux available in the working space.

The stray and fringing flux is generally not useful when it is the intention to have some magnetic material acted on. The quantity and distribution of leakage flux around any magnetic structure will vary widely depending upon the design of the magnetic device. If a magnetic circuit is almost entirely completed with unsaturated magnetic material, and air gaps are relatively short, the leakage flux is small. In many magnetic devices, however, the air gap must be sizable to get the necessary action on the attracted armature. With this the case, leakage flux will be relatively large, and as indicated later in this article, relations dependent upon flux values will be relatively less precise.

CONTROL OF FORCE AND MOTION IN ELECTROMAGNETS. The motion resulting directly from the action of the forces in an electromagnet is generally a linear one. Whether the motion is through a short or long distance, energy up to some limited quantity can be transferred through the magnetic field. Large forces may act through relatively short distances, or if motion through considerable distances is required, only a small force can be exerted. In view of these conditions various designs are created for the

securing of the required force and distance characteristics. By the use of proper links, hinges, and levers, as well as core and frame forms, forces, distances, and directions may be altered in the particular application of an electromagnet.

In the motion of the plunger, clapper, or other moving part of the electromagnet certain features in the design are important. The *initial force* acting must be sufficient to overcome frictional and gravitational forces on the moving part. At the end of the travel of the moving part the *final pull* exerted on it must be sufficient to make the action definite and non-chattering. This is effected by the creation of a good *sealing pull* which holds the moving part firmly at the end of its travel. The travel of the moving part is usually arrested by part of the electromagnet frame, by a magnetic cushion, or mechanically by means of a spring, stop, or dash pot. Certain magnetic devices are designed to utilize the energy resident in the moving part to cause a *hammer blow* as in a relay trip or in the electric hammer.

To make the action of electromagnets quick, positive, and non-sticking, it is common to use a spring or some other energy-storing means against which the electromagnet force must work. By adjusting this stored spring force to exceed any residual forces after current is disconnected, the action of the electromagnet is made positive and definite. When the back force and electromagnet force are about equal, a condition of fluttering or chattering may arise until one of the forces becomes large enough to hold contrary to the other.

The speed of action in an electromagnet is primarily controlled by the mechanical and electrical characteristics of the device. For quick action the self-inductance should be small, the mass to be accelerated small, with little initial friction. These characteristics will permit a quickly rising, relatively large current with a subsequent quick but usually short action. Heavy-duty, long-stroke electromagnets are generally slow-acting, being of relatively large size and large self-inductance.

When the moving part of an electromagnet makes a good physical contact with the poles of the electromagnet a good sealing pull results from the high magnetization set up in the closed magnetic circuit. This condition may give rise to *sticking* when the electromagnet current is cut off. This sticking depends primarily on the remnant magnetism and may be overcome by reversing the polarity for a moment, or by originally limiting the current with an external resistor. A non-magnetic gap or air gap in the magnetic circuit reduces the remnant magnetism and therefore the sticking.

CLASSIFICATION OF ELECTROMAGNETS. The choice of an electromagnet for any particular application depends upon the following factors: (1) voltage available (a-c or d-c), permitted current drain; (2) distance over which electromagnet force must act; (3) speed of action required.

When these factors are known and a suitable type of electromagnet is chosen, the actual design as to dimensions of the various parts is made. This design will consider the size of load, the action distance, speed of action, the excitation, and any limitations placed on the shape and size of the device.

Electromagnets may be grouped in several ways, but a most general classification may be made on the following basis: (1) no moving parts; (2) part moved for holding (portative); (3) part moved through a distance against forces, thus doing work (tractive).

These general forms may be further subdivided in classes as to current used, physical shape, etc. The following brief classification indicates the major forms in each category.

1. *No Moving Parts* (operate on direct current).
   Electrical machine field structures, electromagnets for physical and chemical research.
2. *Portative* (for attracting and holding magnetic materials; operate on direct current, or with alternating current and shading coil.)
   Lifting magnets, magnetic chucks, clutches, couplings and brakes, ore and trash separators, low-voltage release on starting rheostats.
3. *Tractive* (with associated moving parts; operate on direct current and alternating current; various combinations of size of armature, length of stroke, speed of action) and including:
   bells and buzzers; telegraph and telephone relays; current, time, and voltage limit switches and relays; mechanical switch and valve control; and many forms of indicators and magnetic mechanical control.

DESIGN AND CONSTRUCTION. The problem is to construct a coil which, for a given voltage across its terminals, will produce a given number of ampere-turns, and which will not overheat. Usually one or more of the dimensions of the coil are also fixed by the conditions under which the coil is to be used. The following factors must be taken into account in designing a winding:

Insulation from Core; Design of Bobbin. When the core is fixed, two washers of hard rubber or vulcanized fiber are forced on at either end of the core. The core is then insulated with a wrapping of paper, mica, or oiled linen, and is then ready to be wound. When the core is movable, the two end washers are forced on to the ends of a brass tube or a tube made of the same material as the washers. When a metallic tube is used the washers are sometimes made of the same metal. In the case of a quick-acting plunger magnet a metallic bobbin, if used, should be slotted, in order to avoid eddy currents; this also applies to all forms of a-c electromagnets.

Insulation of Wires; Insulation Between Layers; Baking. The wire may be insulated with a cotton, silk, or asbestos wind or by a coating of enamel. In high-voltage solenoids the various layers of wire are insulated from each other by paper, mica, or oiled linen wrappings, or the entire winding is divided into several sections separated by vertical washers of insulating material. The wound coil may be further insulated by dipping it into an insulating varnish in a vacuum or at atmospheric pressure, after which it is either air-dried or baked.

Aluminum wires and ribbons are used extensively by some manufacturers, especially abroad. In this case the layer of oxide on the wire is the only insulation which is used, but inasmuch as this insulation cannot be destroyed by heat, the coils can be run at much higher temperatures, which is of special value for lifting magnets and similar devices. The oxide layer will stand a potential stress of about 0.5 volt.

Temperature Rise of Winding; Watts per Square Inch. The rise of temperature of the winding will depend primarily upon the average rate at which heat is developed by the electric current and the amount of exposed surface from which this heat can be radiated; the temperature rise will also depend upon the depth of winding, the circulation of the air, etc. The hottest spot in the winding should never reach a higher temperature than 105 deg cent. When the interior of the winding is at 105 deg cent the temperature of the external surface, as measured by a thermometer, will usually be much less (15 deg cent less), as will also the average temperature measured by the change of resistance method.

As a rough approximation a solenoid winding should be so designed that the average power developed will not exceed 0.5 watt per square inch of radiating surface for an open winding, and will not exceed 0.7 watt per square inch of radiating surface for an iron-clad solenoid. In figuring the radiating surface of an open winding, the surface of the hole through the solenoid is not included, and the end surfaces are included only when the solenoid is short. By the radiating surface in the case of an iron-clad solenoid is meant the surface of the winding which is in contact with the iron. A radiation of 0.5 watt per square inch and 0.7 watt per square inch for an open and an iron-clad winding respectively corresponds roughly to an average temperature rise of approximately 60 deg cent; for other rates of radiation the temperature rise will be approximately proportional to the watts per square inch radiated.

For short-time service, i.e., when the solenoid is energized only for short intervals with long intervals between the applications of power, the thermal capacity of the solenoid will permit of a greater dissipation of energy in the winding without overheating it.

Space Factors; Round Versus Square Wire; Layer Versus Haphazard Windings. By the space factor of a winding is meant the ratio of the space occupied by the conductors to the total space occupied by the conductors, the insulation on the conductors, and the voids between conductors. The space factor for strips and square wires is greater than for round wires, but strip and square wires are not extensively used in small sizes because of the increased amount of insulation required for a given section of conductor, and because of the tendency of such wires to twist in winding so that they lie upon their corners instead of upon their faces. However, for conductors of larger section than No. 10 A. W. G., square wire is often used.

In winding wires larger than No. 18 A. W. G. it always pays to wind them carefully in smooth layers ("layer" wound), but for smaller sizes used for open solenoids (as distinguished from iron-clad solenoids) the gain in space factor does not as a rule warrant this care and the wires are wound in a more or less haphazard fashion ("haphazard" wound). For iron-clad solenoids, however, a layer winding is always used, for economy of material requires that the winding space be kept as small as possible. The dotted curves A and B in Fig. 3 for haphazard windings are taken from an article by F. A. Willard (*Elec. World*, 1906, Vol. 47, p. 823).

Round wires are sometimes so wound that the wires of one layer lie in the hollows between the wires of the layer underneath; the wires in this case are said to be imbedded. Objections to this procedure, however, are that each layer must be started from the same end and the insulation on the wires becomes tightly compressed and therefore is less

effective; in most instances the extra labor and the diminution of insulating quality offset the small gain in space factor, which seldom exceeds 3 per cent.

The space factor s for a layer winding of round wire without imbedding, and making no allowance for extra insulation between layers, is

$$s = \frac{\pi}{4}\left(\frac{d}{d + 2t}\right)^2 \tag{1}$$

where d is the diameter of the conductor and t the thickness of insulation. Values of s for various sizes of wire and various thickness of insulation are given by the curves in

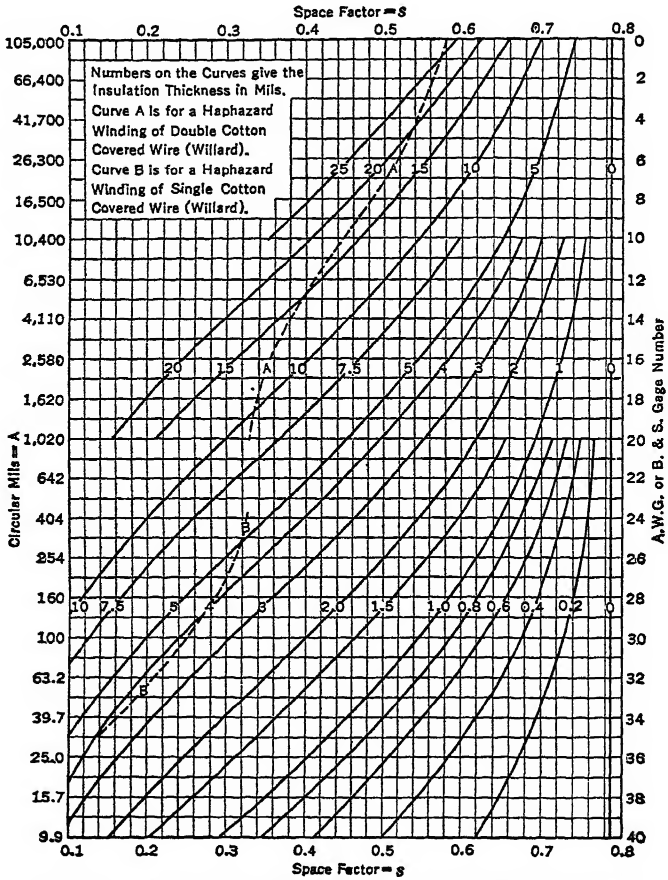

Fig. 3. Space Factor Curves for Close Layer and Haphazard Windings

Fig. 3. The "over-all" space factor, including the allowance for the space occupied by the extra insulation, if any, between layers, is equal to the value of s from these curves multiplied by $(1 - e)$, where e is the ratio of the space occupied by this extra insulation to the total winding space.

Thickness of Insulation. Magnet wire is usually referred to as "single covered," "double covered," and "triple covered," depending upon the number of layers of insulating threads wrapped around it. Different manufacturers use different thicknesses for these layers, with the result that the thickness of the insulation on a "double cotton covered" wire of a given size or gage number depends upon the manufacturer of the wire. Table 1 gives the standard specifications on thickness of insulation for round copper wire.

Table 1. A.I.E.E. Standards Magnet Wire Insulation

Permissible additions to the diameter of bare round
Bare copper wire, with one layer of insulation

Size of Wire A.W.G.	Maximum Addition Single Cotton Covered	* Maximum Addition Single Silk Covered	Size of Wire A.W.G.	Minimum Addition Enamel Covered	Maximum Addition Enamel Covered
0000–8	0.008 in.	.....	8–15	0.0015 in.	0.0025 in.
9	0.007	.....	16–19	0.0012	0.0020

36–40	0.004	0.002	33–34	0.0005	0.0008
			35–36	0.0004	0.0007
			37–38	0.0003	0.0006
			39–40	0.0002	0.0005

* The minimum permissible addition to the diameter of the bare wire shall be 75 per cent of the maximum.

Winding Calculations for Direct-current Solenoids. Round solid wires are assumed throughout. Let

s = space factor, from Fig. 3.

k = ratio of specific resistance of conductor used to that of standard annealed copper at 20 deg cent. For copper of 100 per cent conductivity at 20 deg cent, $k = 1$; for copper of any other per cent conductivity, say C per cent, at any other temperature, say t deg cent, $k = \frac{100}{C} + 0.004\,(t - 20)$. See also Section 14, Art. 50.

A = cross-section of wire in circular mils (= square of diameter in thousandths of an inch).

$n = \frac{1{,}270{,}000\,s}{A}$ = number of conductors per square inch, the square inch being taken perpendicular to the direction in which the wire is wound.

$\rho = \frac{1{,}100{,}000\,sk}{A^2}$ = resistance of the winding per cubic inch of the winding space, excluding the space, if any, occupied by extra insulation between layers; ρ is in ohms.

$w = 0.271\,s + 0.040$ = weight of the winding (copper and cotton insulation) per cubic inch of the winding space, exclusive of the space, if any, occupied by extra insulation between layers; w is in pounds.*

E = impressed volts.

(NI) = ampere-turns, where N is the total number of turns and I the current in amperes.

p = allowable watts per square inch of radiating surface (may be taken approximately as 0.5 for open and 0.7 for iron-clad solenoids, see above).

S = radiating surface, in square inches, calculated as described above under Temperature Rise of Winding.

l = mean length of turn in inches (see Fig. 4 for a simple solenoid).

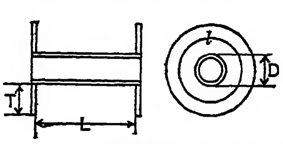

FIG. 4. Winding Form for Simple d-c Solenoid

T = depth of winding space in inches (see Fig. 4), excluding the space occupied by the extra insulation, if any, between layers.

L = length of winding space in inches (see Fig. 4).

$V = LlT$ = volume of winding space in cubic inches, excluding space occupied by the extra insulation, if any, between layers.

* This formula also holds approximately for other kinds of insulation and for most alloy resistance wires. Calling g_c the specific gravity of the conductor and g_i the specific gravity of the insulation, the exact formula is

$$w = 0.0362\,(g_c - g_i)s + 0.0284 g_i$$

Underhill gives g_i as 1.6 for asbestos, 1.4 for cotton, and 1.0 for silk.

The problem is usually to find the size of wire and necessary winding space for a coil which will give, without overheating, a required number of ampere-turns (NI) at a given impressed voltage E. The diameter of the core or spool is also usually known, or at least must not exceed certain fairly well-defined limits, depending upon the service for which it is to be used. The procedure is then to assume a reasonable value for the mean length of turn l. The size of wire is then immediately fixed by the relation

$$A = \frac{kl(NI)}{1.16E} \tag{2}$$

From Fig. 3 the corresponding size of wire (A. W. G.) and the corresponding space factor s may then be found.

The volume V and radiating surface S of the coil must then satisfy the relation

$$\frac{LTS}{l} = \frac{k(NI)^2}{1{,}470{,}000\ ps} \tag{3}$$

The length L and depth T of the winding space must be so chosen that this relation will be satisfied; as a rule this can be done only by cut and try. Note that changing the depth T of the winding space will also change the mean length of turn l, unless the diameter of the core or spool is so altered as to keep l constant. The cross-section of the wire varies directly as l, as shown by eq. 2, and therefore the value of the space factor s to be used in eq. 3 will depend upon l, but only to a slight extent except in very small wires.

Having determined the cross-section of the wire (A), the mean length of turn (l) and the dimensions (L and T) of the winding space so that both (2) and (3) are satisfied, the total number of turns in the winding will be

$$N = nLT = \frac{1{,}270{,}000\ sLT}{A} \tag{4}$$

and the current is then equal to the given number of ampere-turns divided by N and the total length of wire is equal to Nl.

The total resistance r and total weight W (including insulation) of the wire may then be found directly from a wire table, or may be calculated from the formulas

$$r = \rho V = \frac{klN}{1.16A} = \frac{1{,}100{,}000 skLTl}{A^2} \tag{5}$$

$$W = wV = (0.271s + 0.040)LTl. \tag{6}$$

See note at bottom of preceding page regarding w.

Calculation of Open Solenoid of Circular Cross-section. In the case of a coil wound on a spool of diameter D, see Fig. 4, the mean length of turn is $l = \pi(D + T)$. Assuming that the outside cylindrical surface of the winding is the only radiating surface, which is only approximately true, as pointed out above, $S = \pi(D + 2T)L$. Whence, putting

$$Q = \frac{k(NI)^2}{1{,}470{,}000ps} \tag{7}$$

the required length of coil for a given diameter of core D and depth of winding T is

$$L = \sqrt{\frac{(D + T)Q}{(D + 2T)T}} \tag{8}$$

When L is given instead of T, then the required depth of winding is

$$T = \frac{1}{4}\left[\left(\frac{Q}{L^2} - D\right) + \sqrt{\left(\frac{Q}{L^2} - D\right)^2 + \frac{8QD}{L^2}}\right] \tag{9}$$

In either case, the number of turns, total resistance, weight, etc., are found as described above for the general case.

Example. Required to design an open solenoid 10 in. long and having an internal diameter of 1.5 in., to give 12,000 amp-turns at 110 volts, the heat developed not to exceed 0.5 watt per square inch of radiating surface (taken as the outside cylindrical surface of the coil). Assume a mean length of turn equal to 10 in., then from eq. 2 the required cross-section of the wire, assuming copper at 70 deg cent, is $A = 1130$ cir mils. From Fig. 3 the space factor is then $s = 0.62$, assuming single cotton-covered wire with 2-mil insulation wound in layers. From eq. 7 the value of Q is then $Q = 380$, whence from eq. 9 the required depth of winding is $T = 2.36$ in. The actual mean length of turn is then $l = 12.1$ in. which substituted in eq. 2 gives, for the cross-section of the wire required, $A = 1368$. This wire section gives a space factor, see Fig. 3, of $s = 0.63$, which agrees practically with the value $s = 0.62$ used above. The nearest commercial size of wire is No. 19 A. W. G., having a cross-section of 1288 cir mils. If this size of wire is used the actual ampere-turns will be $NI = 11{,}300$. From eq. 4 the total number of turns will

then be $N = 14{,}700$, and from eq. 5 the total resistance will be $R = 143$ ohms. The current is then $I = 0.77$ amp. The total weight of the winding is then, from eq. 6,

$$W = 60 \text{ lb}$$

14. ELECTROMAGNETS, LIFTING AND PLUNGER

(See also Section 3, Electricity and Magnetism, Principles of.) A solenoid provided with a movable magnetic core, or with a fixed core and movable "armature," serves as a very convenient means of causing an electric current to produce a direct mechanical pull. This principle is utilized in various forms of lifting magnets, relays, contactors, electric brakes, clutches, etc. In the paragraphs following are given the formulas required in calculating the pull of various kinds of electromagnets in terms of their dimensions and ampere-turns, and also a brief statement of the applications of the various types.

Approximation of Formulas; Leakage Factor. In applying the formulas given below, it should be noted that in general the effect of magnetic leakage is neglected. The leakage factor varies so greatly with the different forms of electromagnets that it is impossible to go into this matter in detail in the limited space available for this article. The designer, in making an allowance for leakage, has to rely chiefly upon his previous experience with other magnets of the same general form and dimensions. Merely as a rough guide to the designer who has not had this experience, it may be stated that for magnets of reasonable shape and dimensions, the formulas for pull given below may be relied upon to give the actual pull with an error of less than ± 10 per cent, the actual pull usually being less than the calculated pull. Under certain conditions the agreement between the actual pull and calculated pull may be much closer than the difference just stated.

SIMPLE SOLENOID AND PLUNGER. The simplest type of electromagnet is a simple solenoid, as shown in Fig. 5, consisting of a cylindrical coil of circular or rectangular

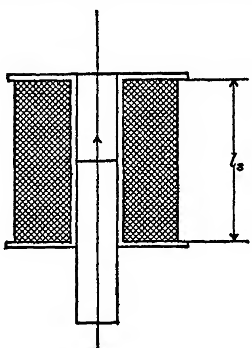

FIG. 5. Simple Electromagnet

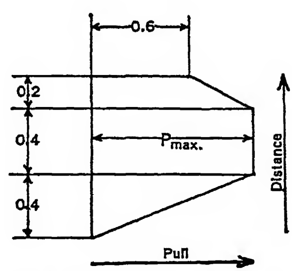

FIG. 6. Approximation Variation of Pull During Stroke for Simple Electromagnet

section and an iron plunger which fits into the inside of this coil. When current passes through the coil the plunger is attracted.

VARIATION OF PULL OF SIMPLE SOLENOID DURING THE STROKE. The pull of the simple solenoid varies between approximately zero when the plunger is at the lower end of the coil and a maximum which is nearly constant over approximately 40 per cent of the length of the coil. The maximum is reached when the plunger has entered the coil a distance of approximately 40 per cent. When the plunger has entered the coil 80 per cent of its length, the pull decreases again, reaching a value of about 0.6 of the maximum pull when the plunger is even with the top of the coil. The approximate pull variation is shown in the diagram, Fig. 6, of course the actual variation is a smooth curve, such as shown by curve A in Fig. 10.

Calculation of Pull of Simple Solenoid. The calculation of the exact pull of such a magnet is very complicated, being dependent not only upon the ampere-turns, but also upon the shape of the coil, the size and length of the plunger, and the induction in same. For practical purposes the maximum pull, when the plunger is at least as long as the coil, can be represented by the formula

$$P_1 = \frac{cANI}{l_s} \text{ pounds} \tag{10}$$

where c = the pull in pounds per square inch per ampere-turn per inch of coil length;
A = the area of the cross-section of plunger, in square inches;
I = the current in the coil, in amperes;
N = the number of turns in the coil;
l_s = the length of the coil, in inches.

It has been found that c varies between 9×10^{-3} and 10.5×10^{-3} when the plunger is *magnetically saturated*. For practical purposes sufficiently close results for a *saturated* plunger are obtained if c is taken equal to 10^{-2}. The formula shows that the maximum pull for a *saturated* plunger is directly proportional to the current, which makes this type of magnet especially suitable for relays and instruments which should be very sensitive. When the flux density in the plunger is well below the knee of the B–H curve, the factor c varies almost directly as the ampere-turns, and the maximum pull, therefore, varies approximately as the square of the ampere-turns.

The pull at any point in the stroke for a *saturated* plunger may then be expressed by the formula

$$P_1 = \frac{10^{-2}ANI}{l_s} \cdot k \text{ pounds} \tag{11}$$

where k is a factor which gives the ratio of the pull at any point of the stroke to the maximum pull; Fig. 6 gives the approximate value of k at various points of the stroke.

IRON-CLAD ELECTROMAGNET WITH FLAT-END PLUNGER. The simple solenoid is a very inefficient type of magnet, because a large percentage of the reluctance of the magnetic path is found in the long air path outside the coil. Therefore, the plunger magnet is modified by putting an iron return circuit around the outside of the coil, thus reducing considerably the reluctance of the path and increasing the work which can be obtained with a certain amount of power, and with a certain expenditure of energy in the coil. Fig. 7 shows this type of "iron-clad" magnet. In its highest position the plunger

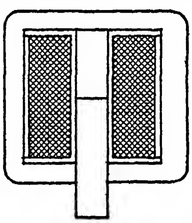

FIG. 7. Iron-clad Electromagnet, Flat-end Plunger

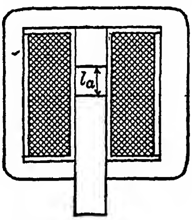

FIG. 8. Iron-clad Electromagnet, with Stop

strikes against the frame, so that in reality the magnet represented is a special form of magnet with stop, which is described below. If it is desired to have the pull decrease towards the end of the stroke, a hole similar to the one on the lower end is drilled in the upper end of the frame, and the plunger permitted to protrude through it.

Use of Stop to Increase Pull. The total pull on a plunger depends on the total number of flux lines which pass through it. For a given number of ampere-turns the total number of flux lines may be increased by decreasing the reluctance of the magnetic circuit. This reluctance may be still further reduced by using a plug or stop in the upper part of the solenoid of such a length that the air gap is central to the coil for the maximum travel which is required. This form is shown in Fig. 8.

Pull of Stop on Plunger; "Air-gap Pull." The pull P_2 between the stop and plunger may be expressed by the formula

$$P_2 = \frac{B^2A}{72 \times 10^6} \text{ pounds} \tag{12}$$

where B is the flux density in the air gap * perpendicular to the end surface of the plunger, in lines (maxwells) per square inch, and A the area of the end of the plunger, in square inches. The value of B may be calculated from the ampere-turns of the coil and the dimensions of the magnetic circuit in the same manner as the flux due to the field coils of a generator is calculated. Or, neglecting leakage and the reluctance of the iron part of the path, B may be calculated approximately from the formula

$$B = \frac{3.19NI}{l_a} \text{ lines per square inch} \tag{13}$$

* Strictly, B in this formula is the actual air-gap flux density less the flux density which would be produced by the solenoid were there no iron whatever in its magnetic circuit. This correction however, is smaller than the probable error in calculating B and may therefore be neglected.

where NI is the total ampere-turns of the coil and l_a is the length of the air gap in inches. Combining eqs. 12 and 13 gives*

$$P_2 = 1.4 \times 10^{-7} A \left(\frac{NI}{l_a}\right)^2 \text{ pounds} \tag{14}$$

This pull of the stop on the plunger is usually referred to as the "air-gap pull." The actual variation of this air-gap pull with the length of the air gap, for a particular magnet, is shown in curve B, Fig. 10.

Total Pull of Iron-clad Solenoid with Stop. The total pull of the iron-clad solenoid with stop may be looked upon as due to two components, the solenoid effect P_1 given by eq. 11 and the pull P_2 between stop and plunger given by eq. 14; hence the total pull is

$$P = 10^{-2} ANI\left(\frac{k}{l_s} + \frac{1.4 \times 10^{-5} NI}{l_a^2}\right) \text{ pounds} \tag{15}$$

When the air gap is short and at the center of the solenoid $k = 1$. The variation of this total pull with length of air gap for a particular electromagnet is shown in curve C, Fig. 10.

IRON-CLAD SOLENOID WITH CONED PLUNGER. It will be noted that for a given air-gap pull P_2, the ampere-turns required are directly proportional to the length of the air gap. If, therefore, for the same stroke the length of the path for the magnetic lines through the air gap can be reduced, the pull for the same ampere-turns will be increased, or if the pull remains constant the ampere-turns to obtain it can be decreased. This is accomplished by coning the end of the plunger, as shown in Fig. 9. For such a magnet the stroke should not be much in excess of the plunger diameter, as the leakage increases considerably with longer strokes, and this defeats the object of the coning. As the induction in the iron plunger is greater than the induction in the air gap, there is a limit to the practicable value which may be given to the cone angle; this limit is about reached for cast iron for a cone angle of 28 deg and for cast steel for a cone angle of 19 deg.

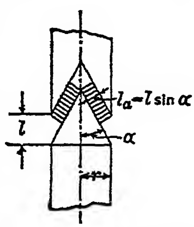

FIG. 9. Iron-clad Electromagnet, with Coned Plunger

"Air-gap Pull" on Coned Plunger. In the following it is assumed for simplicity's sake that a uniform flux at right angles to and distributed over the entire surfaces of the cones passes between plunger and plug. This is not strictly correct, especially for long strokes and the pull calculation is therefore only approximately correct.

Let l = length of stroke, in inches;
A = total cross-section of plunger, in square inches, $= \pi r^2$ where r is the radius of the plunger, see Fig. 9;
α = angle of the cone, in degrees, see Fig. 9;
NI = total ampere-turns of coil.

Then the flux density in the plunger is

$$B_i = \frac{3.19 NI}{l \sin^2 \alpha} \text{ lines per square inch} \tag{16}$$

and the air-gap pull in the direction of the stroke is

$$P_2 = 1.4 \times 10^{-7} A \left(\frac{NI}{l \sin \alpha}\right)^2 \text{ pounds} \tag{17}$$

The solenoid pull, as found by experiment, is practically the same as for a flat-end plunger, eq. 10. Whence the total pull on the coned plunger is

$$P = 10^{-2} ANI \left(\frac{1}{l_s} + \frac{1.4 \times 10^{-5} NI}{l^2 \sin^2 \alpha}\right) \text{ pounds} \tag{18}$$

where l_s is the length of the solenoid winding assuming the gap at the center of the solenoid ($k = 1$).

Note that $l \sin \alpha = l_a$ is the "effective" length of the air gap, i.e., the length perpendicular to the surface of the cone. Hence, comparing with eq. 15, it is seen that the pull on a coned plunger for the same effective air gap is the same as on a flat-end plunger, but the length of the stroke is increased in the ratio of $\dfrac{1}{\sin \alpha}$. Comparing eq. 16 with eq. 13, it is seen that this advantage is gained by increasing the flux density in the plunger by the square of $\dfrac{1}{\sin \alpha}$. For small air gaps, therefore, the coned plunger becomes satu-

* This formula applies only when the flux density in the magnetic circuit is below the point of saturation.

rated much more quickly for the same current than does the flat-end plunger, and the leakage and the reluctance of the iron part of the path produce an appreciable effect, causing the pull to become almost constant for small air gaps instead of increasing as shown by the approximate equation 18. This effect is clearly shown by the curves D and E in Fig. 10.

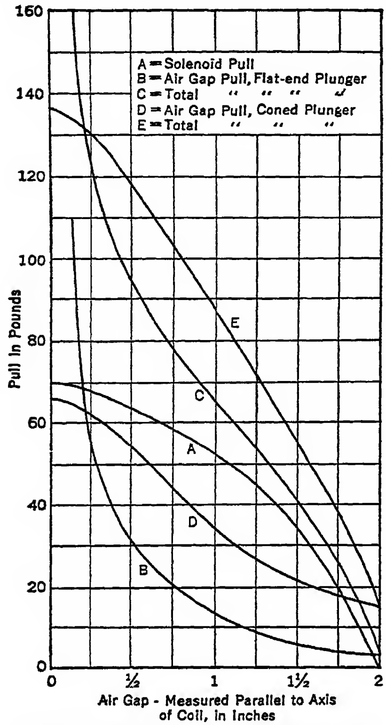

Fig. 10. Relative Pulls of Electromagnet Plungers

HORSESHOE-TYPE ELECTROMAGNETS. Another type of electromagnet which is used quite extensively is the horseshoe type, shown in its simplest form in Fig. 11. This magnet is not suitable for very long air gaps, because the leakage increases very rapidly with increasing distance between armature and poles. The total pull on the "armature" K of such a magnet, neglecting the leakage, may be expressed approximately by the relation

$$P = 2.8 \times 10^{-7} A \left(\frac{NI}{2l_a + l'}\right)^2 \text{ pounds} \quad (19)$$

where A = cross-section of each pole, in square inches; NI = total ampere-turns; l_a = length of each air gap in inches; and l' = length of air gap equivalent to the reluctance of the iron. This last depends on the permeability and dimensions of the iron part of the circuit; calling l_i the mean length of this iron circuit and μ its permeability, and assuming the mean cross-section of this path to be the same as the cross-section A of each pole, then $l' = l_i/\mu$. A more exact calculation of the pull may be made by calculating, as for a generator field, the ampere-turns required to establish a given flux density of B lines per square inch in the gap, and then applying eq. 12 to determine the pull.

SPEED OF MOVEMENT OF PLUNGER. In order to obtain quick action, the flux, upon closing the circuit, should reach its full value in as short a time as possible. The flux being a function of the current, the speed depends upon the rapidity with which the current reaches its full value. The time required for the current to reach its full value depends upon the quotient of the inductance L divided by the "effective" resistance r of the circuit. The larger this ratio L/r, which is called the "time constant" of the circuit, the longer the time required for the current to reach its full value. The inductance L is proportional to the square of the number of turns in the solenoid winding and inversely proportional to the total reluctance of the circuit. The effective resistance r depends not only upon the d-c or ohmic resistance of the winding, but also upon the eddy currents and hysteresis loss set up when the current is changing.

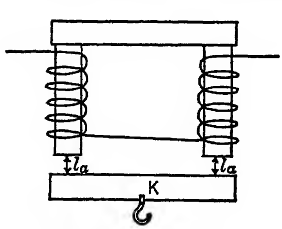

Fig. 11. Horseshoe Type Electromagnet

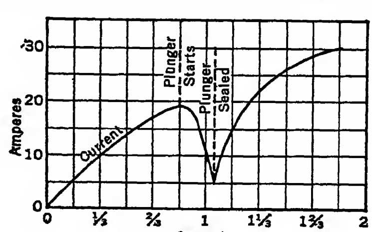

Fig. 12. Current-time Characteristic of D-c Electromagnet

In Fig. 12 is given current-time curve showing the change of the current during the

switching-in period of a d-c magnet. It will be seen that, after the closure of the circuit, the current first rises to a certain value which corresponds to a flux just sufficient to cause a movement of the armature and lift the plunger. As the plunger moves the flux increases, thereby causing a counter electromotive force, which tends to reduce the current. This counter emf depends upon the speed of the plunger. In the case shown the current drops off continuously until the plunger strikes against the stop, at which moment it has a value of approximately one-third of the value which started the motion of the plunger. After the plunger has come to rest, the current again increases and gradually reaches the value which is dependent upon the terminal voltage and the resistance of the coil.

Methods of Obtaining Quick Action. To reduce the eddy-current effect, the cross-section of the magnet frame should be as small as consistent with other considerations. Where very quick action is required it is sometimes advisable to slot this frame at right angles to the direction of the eddy currents or laminate it similar to transformers. In such cases it is also advisable to eliminate the brass tube on which the coil is very frequently wound and which acts as a guide for the plunger, or to slot this brass tube parallel to its axis. It is also advisable to slot or laminate the plunger.

Another method of obtaining quick action is to impress at the start a high voltage on the coil and insert resistance into the circuit of the coil as the plunger rises, in order to protect the magnet from overheating. This reduces the ampere-turns at the end of the stroke, which is permissible in most cases, because usually the pull of the magnet increases very rapidly toward the end of the stroke, as is indicated by the formulas given above.

ALTERNATING-CURRENT ELECTROMAGNETS. Electromagnets for producing a mechanical pull may also be designed to operate on alternating current. The flux in an a-c magnet passes through zero twice per cycle. The pull, which varies with the square of the current, therefore becomes zero twice every cycle, and it can be shown that it also varies according to a sine curve when the current is sinusoidal. The average effective pull is one-half of the maximum pull. Whenever the pull is less than the load, there is a tendency for the plunger to move away from the stop, and this causes rattling or humming of the magnet. This humming may be overcome in different ways, one method being to use a "shading coil," described below.

Polyphase Electromagnets. It can be shown that if three magnets are used and each is supplied with current from one phase of a three-phase source, or if two magnets are used and each is supplied with current from one phase of a two-phase source, then the resultant pull will be constant at any moment, and if the plungers are rigidly connected there will then be no chattering. The most common form of three-phase magnet is shown in Fig. 13. This consists of a core having three poles and a plunger of similar construction. Over each pole there is wound a coil which is supplied from one of the three phases of the circuit. There are various modifications of the polyphase magnet, but their general principle is the same. In calculating the total pull, the pull of each pole is figured separately and the several pulls, which are equal to one another, are combined vectorially, since they differ in time phase.

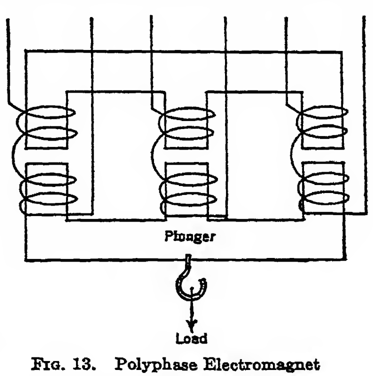

FIG. 13. Polyphase Electromagnet

Calculation of Pull of Single-phase Electromagnets, or of One Phase of Polyphase Electromagnets. The formulas for pull given above for d-c electromagnets also hold for a-c magnets, provided I is taken as the effective value of the current, B as the effective value of the flux density, and P as the average or effective value of the pull.

In contrast to the d-c electromagnet, the flux in an a-c electromagnet for a given impressed emf is approximately constant irrespective of the length of the air gap. This is due to the fact that the opposition to the flow of current through the winding is due almost entirely to the back emf, due to the alternation of the flux, and only to a very small extent to the resistance of the winding, the action in this respect being similar to that of a transformer (q.v.) or induction motor. The back emf being practically equal to the impressed emf, the flux producing this back emf is also proportional to the impressed emf, and is therefore practically constant when the impressed emf is constant.

Since the flux remains practically constant, the current I, as may be seen from eq. 13, must vary approximately proportionally to the length of the air gap l_a; this propor-

tionality holds only approximately, since eq. 13 neglects the magnetic leakage and the reluctance of the iron part of the magnetic circuit. The actual variation of the current with the length of the air gap for a particular a-c electromagnet is shown in Fig. 14.

Using the same notation as used above for d-c electromagnets and in addition putting E = effective value of impressed voltage per phase, and f = frequency of impressed voltage in cycles per second, the current taken by each phase of the magnet, neglecting the iron losses, leakage, and reluctance of the iron part of the magnetic circuit, will be

$$I = \frac{10^7 E l_a}{2fNA^2} \quad \text{amperes} \tag{20}$$

A more accurate calculation of the current, taking into account the losses and the magnetic leakage, may be effected by the method used for calculating the current in a transformer.

Substitution of the value of the current given by eq. 20 in eq. 15 for the total pull on a plunger with a flat end gives the approximate formula

$$P = \frac{10^5 E}{2fN}\left(\frac{kl_a}{l_s} + \frac{72E}{fNA}\right) \quad \text{pounds} \tag{21}$$

This equation also applies to a coned plunger, when l_a is taken equal to the length of the air gap perpendicular to the face of the cone.

Fig. 14 shows the pull curve of an a-c magnet with flat-end stop and plunger. It will be noted that the current is roughly proportional to the air gap. The solenoid pull reaches a maximum at an air gap of about 2 1/4 in. and then falls again approximately proportional to the air gap; the air-gap pull is constant over a wide range of the travel. The result is a total pull curve which has a maximum at approximately 2 1/4 in. and which drops until an air gap of approximately 3/4 in. is reached, and from there on it increases again, due to the increase of the air-gap pull, which is caused by the diminution of the leakage flux as the air gap decreases.

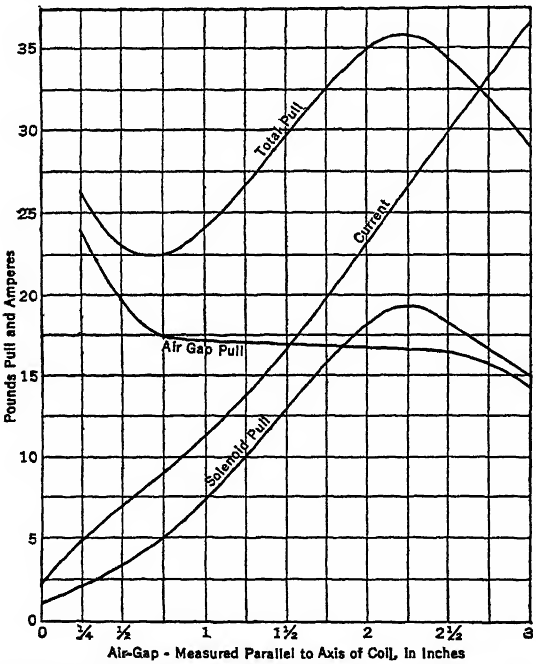

FIG. 14. Pull and Current Curves of a-c Magnet. Length of solenoid 5 inches; internal diameter of solenoid 3 inches; external diameter 4 1/2 inches; diameter of plunger 2 3/8 inches; stop projects 1 1/2 inches inside of coil; turns 144; voltage 220; frequency 60 cycles per second

Limiting Flux Density and Losses in A-c Electromagnets. Attention must be paid to the fact that the iron losses, like those of the transformer, increase with the flux density, and therefore the design must be such that the flux density is not too high. The flux density in the iron in the case of a flat-end plunger, from eq. 13, which neglects the magnetic leakage and reluctance of the iron part of the magnetic path, is

$$B = \frac{1.6 \times 10^7 E}{fNA} \quad \text{maxwells per square inch} \tag{22}$$

and in the case of a coned plunger, under the same assumptions, from eq. 16 is

$$B = \frac{1.6 \times 10^7 E}{fNA \sin \alpha} \quad \text{maxwells per square inch} \tag{23}$$

where α is the cone angle, see Fig. 9.

These relations are approximate only. The magnetizing component of the exciting current, and from it the flux density can be more accurately calculated by the methods employed in the design of transformers or induction motors.

The iron and copper losses can also be calculated by similar methods, and from these losses the energy component of the exciting current can be determined. The total current and power factor of the electromagnet can then be deduced.

Shading Coil for Single-phase Electromagnets. The humming of single-phase magnets may be greatly reduced by introducing a so-called "shading coil" in the pole face. This shading coil is nothing more than a short-circuited secondary winding, consisting of one or more turns, which encloses only part of the total flux passing through the plunger. Owing to the leakage reactance of this turn, the current induced in it is out of phase with the inducing flux, so that at the moment when the inducing flux, due to the main winding, is zero, there still remains a flux due to the current in the shading coil, which flux produces a pull. The result is that the combined pull from the main flux and the shading coil flux never becomes zero. Fig. 15 shows the arrangement of the shading coil. This coil is mounted in the plunger or in the plug close to the pole face, in order to reduce the length of the path for the magnetic lines which are interlinked with the shading coil. Naturally the shading coil has no effect with long air gaps, and it is therefore imperative that a good magnetic contact be obtained when the plunger is in the sealed position to get the greatest possible effect of the shading coil.

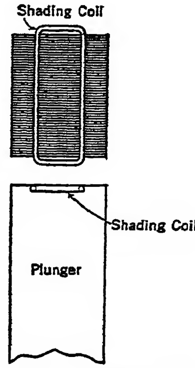

Fig. 15. Shading Coil

Incidentally the shading coil also increases considerably the maximum pull for a given impressed emf as the maximum pull is also due to the combined main and local flux. As an example, a plunger magnet without shading coil, which gave a minimum pull of zero and a maximum pull of 28 lb, had, after the introduction of the shading coil, a minimum pull of 18 lb and a maximum pull of 143 lb.

15. INDUCTION COILS

(See also Section 3.) An induction coil is a device which transforms a low direct emf to a high alternating emf of unsymmetrical form. The single-winding coil, called a primary coil, is used extensively in gas-engine ignition and in automatic gas lighting, and the double-winding coil, called a secondary coil, is used for the excitation of x-ray tubes, gas-engine ignition, automatic gas lighting, electrotherapeutics, and wireless telegraphy.

PRIMARY INDUCTION COIL. The primary induction coil consists of a single coil wound upon an iron core made up of a compact bundle of soft-iron wires. To obtain a spark from such a coil it is connected in series with a battery and some kind of "make-and-break" contact. When the circuit is closed, the current increases gradually according to the expression,

$$i_t = \frac{E}{r}(1 - \epsilon^{-rt/L})$$

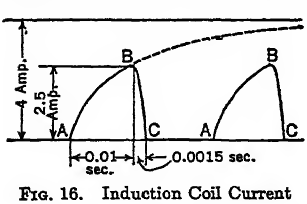

Fig. 16. Induction Coil Current

where i_t equals the current at any time t seconds after the circuit is closed, E equals the emf of the battery, r equals the resistance in ohms and L equals the inductance in henrys of the entire circuit, and ϵ the base of the natural system of logarithms. The shape of the current curve at "make" is shown in the curve AB (Fig. 16),* which is an oscillograph record taken when an emf of 4 volts is impressed upon a primary coil of 1-ohm resistance and 0.01-henry inductance.

If the circuit is opened when the current reaches some value, such as B (Fig. 16), the current decreases rapidly to zero as shown in the curve BC. Since the emf induced in such a coil at any instant equals $L\frac{di}{dt}$ when the current falls from B to C, the emf, induced in the coil will be many times that of the battery emf and a spark will be established between the open contacts at "break." For use in connection with gas engines the "make-and-break" contacts are located within the cylinder. Reliable ignition is

* This and the following oscillograph records are due to Bailey, B. F., *Elec. World*, 1910, Vol. 55, p. 948.

obtained when about 0.02 joule is dissipated in the spark at "break." Since the energy dissipated as heat in the spark is converted from the electromagnetic energy stored up in the coil, it follows that the coil must have an inductance and carry a current at "break" such that the energy stored up, i.e., $1/2\, LI^2$, will exceed the required value of 0.02 joule. In practice it is customary to design the coil and time of contact so that $1/2\, LI^2$ equals about 0.04 joule, such coils having an efficiency of about 50 per cent. One-half of the energy put into the coil is then used up in heating the conductors and metallic parts by I^2R and hysteresis losses.

SECONDARY INDUCTION COIL. The secondary coil has two separate windings wound about an iron core, one of few turns called the primary winding and the other of many turns called the secondary winding. The primary winding is connected in series with a battery and an interrupter (described below). The spark is produced between the terminals of the secondary winding. In most cases a condenser is shunted across the interrupter to prevent sparking at that point. Since the emf induced in each turn linked by the magnetic flux is the same, the emf induced in the secondary winding, neglecting leakage, will equal $\frac{N_s}{N_p}$ times that induced in the primary winding, where N_s and N_p equal the respective number of turns on the secondary and primary windings. Secondary coils which give sparks as long as 5 ft have been constructed in this manner.

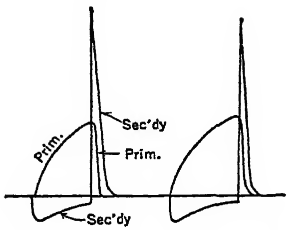

FIG. 17. Interrupter Current; No Condenser

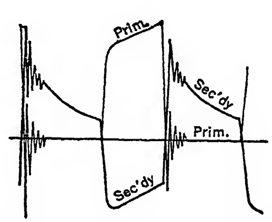

FIG. 18. Interrupter Current at Break; Condenser Shunt

Effect of Shunting Interrupter with Capacitance. When the interrupter is shunted by a capacitance the emf induced in the secondary winding becomes oscillatory. This effect of the capacitance is well shown in the oscillograph records given in Figs. 17 and 18. In each case a high non-inductive resistance is connected across the secondary terminals, and the curves indicate the variation of the primary current and the secondary emf. In Fig. 17 the interrupter is unshunted by a condenser, and as a result the secondary emf increases at "break" and decreases to zero without oscillation. In Fig. 18 the interrupter is shunted by a condenser and the secondary emf becomes oscillatory. The form of the emf curve in any actual case is not shown accurately by Fig. 18 except at the time of "break," since the resistance between the terminals of a spark gap decreases rapidly after the spark is established. In Fig. 19 a low resistance is connected across the secondary terminals and shows the general form of the emf curve after the spark is established.

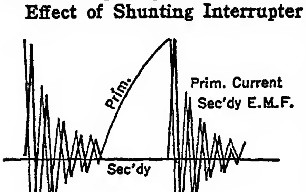

FIG. 19. Interrupter Current after Establishment of Arc; Condenser Shunt

Although not shown by the curves owing to difference in scale, the capacitance shunted around the interrupter also increases the secondary emf above the value obtained without the capacitance. Assuming that no spark is formed at the interrupter, it may be shown that the emf of the secondary equals $\frac{N_s}{N_p}\sqrt{\frac{L}{C}}\,I_b$, where L equals the inductance of the primary in henrys, C equals the capacitance of the condenser in farads, and I_b equals the primary current at "break" in amperes. If C is made so low that a spark appears at the interrupter, the above formula no longer holds and the secondary emf will be greatly reduced. C should then be made as small as possible but of sufficient size to suppress the spark at the interrupter.

Insulation. The conductors in the secondary winding must be heavily insulated to

withstand the very high emf induced in that winding. In most cases a double-covered silk insulation impregnated with some insulating compound is used. In large induction coils the secondary winding is built up of several flat coils insulated from each other by ebonite or fiber disks. The coils are so wound that the electrical connections are made alternately at the top and at the bottom of the respective coils.

Dimensions of 3-inch Coil. The general dimensions of parts of a 3-in. induction coil, as reported by S. R. Bottone, *Radiography* (London, 1898). are given following· Iron, bundle of No. 20 (A. W. G.) annealed iron wire, 1 1/4 in. diameter. 13 in. long. Primary winding, four layers of No. 12 double silk-covered copper wire, about 4 1/4 lb. Ebonite tube over primary, 12 in. long, 2 in. inside diameter, 2 1/2 in. outside. Two ebonite heads, 5 in. square, 1/2 in. thick. Seven vulcanized fiber circlets (for sections), 4 1/2 in. diameter, 1/8 in. thick, 2 1/2 in. central aperture. Secondary winding, 4 lb No. 36 double-silk-covered wire. Platinum-tip contact breaker, height from base to center of iron hammer, 2 1/2 in., size of iron head of hammer 3/4 in. diameter, 3/4 in. long. Base (fitted with false bottom to contain condenser), 18 in. long by 9 in wide by 2 3/4 in. deep. Condenser, 144 sheets of tin foil, size 6 by 12 in., interleaved with 144 sheets of paraffined paper 8 by 13 in.

Dimensions of 6-inch Coil. Similar dimensions for a 6-in. induction coil, as reported by Bottone, are given following: Iron bundle of No. 16 (A. W. G.) annealed iron wire, 1 1/2 in. diameter, 15 in. long. Primary winding, four layers of No. 12 double silk-covered copper wire, about 5 lb. Ebonite tube over primary 14 in. long, 2 1/4 in. inside diameter, 2 3/4 in. outside. Ebonite heads 6 in. square, 3/4 in. thick. Seven vulcanized fiber circlets 5 1/4 in. diameter, 1/8 in. thick, with 2 3/4 in. central hole. Secondary winding, 7 lb No. 38 double-silk-covered copper wire. Platinum-tip contact breaker, height from base to center of hammer, 3 in. size of hammer head, 1 in. diameter, 1 in. long. Base (fitted with false bottom to contain condenser), 20 in. long by 10 in. wide by 3 1/2 in. deep. Condenser, 144 sheets of tin foil, size 6 by 12 in., interleaved with 144 sheets of paraffined paper, 8 by 13 in.

Interrupters. An interrupter should be so designed that it will close the circuit for a definite time by easy adjustment and will open the circuit at the end of that time as quickly as possible. Two distinct types, the mechanical and the electrolytic interrupter, are in common use. Mechanical interrupters may be divided into the following forms. hammer, atonic, commutator and mercury interrupters. Of the electrolytic interrupters the Wehnelt type is the most popular.

Hammer Interrupter. In the hammer interrupter, shown in Fig. 20, the circuit is opened at A when the core B attracts the iron mass C mounted at the free end of the

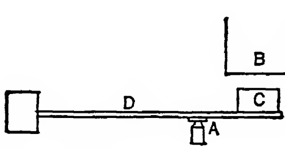

Fig. 20. Hammer Interrupter

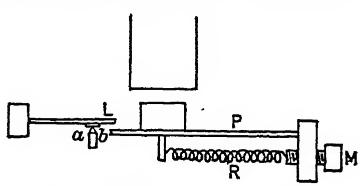

Fig. 21. Atonic Interrupter

spring blade D. Since the core attracts the iron mass only when the circuit is closed and loses its attraction when the circuit is opened, the spring blade is set in vibration and opens and closes the circuit in rapid succession. This type is used extensively in connection with small coils. The contacts at A are usually tipped with platinum to withstand the intense heat developed by sparking. The rapidity of the " break " is not great enough for large coils, and when a large current must be broken, trouble is experienced in keeping the contact points in good condition.

Atonic Interrupter. In the atonic interrupter, shown in Fig. 21, the free end of the iron strip P is attracted as in the hammer interrupter and is returned to its original position by the spring R. The circuit is opened at the contacts ab when the free end of P strikes the blade L. Interrupters constructed in this manner open the circuit quicker than do the hammer type since the attracted member is moving faster at the instant of " break." The period of the atonic interrupter may be varied within wide limits by regulating the tension on the spring R by means of the thumb-screw M.

Commutator Interrupters are often used when the primary current is too large to be broken by the hammer or atonic interrupters. A brush bearing upon a revolving disk, built up of conducting and insulating segments, makes and breaks the circuit at any desired rate, depending upon the speed of the motor which drives the disk.

Mercury Interrupters are specially adapted to circuits of high emf. In the *plunger*

type a pointed electrode is alternately immersed and withdrawn from a cup of mercury, the moving electrode being set in vibration magnetically as in the hammer interrupter, or by the positive action of a cam driven by a motor. The mercury cup is covered with a layer of oil so that the spark is quickly extinguished when the moving electrode is withdrawn into the oil. In the *turbine* type a small stream of mercury is directed upon the periphery of a revolving toothed wheel. The circuit is made when the mercury stream strikes a tooth and is broken when the mercury stream passes through a slot between the teeth. The toothed wheel is rotated at high speed by a motor which also drives a small mercury pump.

Wehnelt Interrupter. The Wehnelt interrupter has two fixed electrodes which are immersed in dilute sulphuric acid. The anode consists of a small platinum wire insulated by glass except at its tip end. The cathode usually consists of a sheet of lead. If the electrolyte is well circulated, an interrupter of this kind will give about 450 interruptions per second with 24 volts impressed upon the primary circuit. When used with large coils the electrolyte heats up quickly, and a cooling coil is sometimes immersed in the electrolyte to control the temperature.

Tesla Coil. In some cases, as in wireless telegraphy, electrotherapeutics, etc., where a unidirectional emf is not required, but an emf of high frequency is desired, a Tesla coil may be used in place of an induction coil. The construction of a simple Tesla coil is shown in Fig. 22. In the primary circuit a primary winding of few turns and a small spark gap are shunted by a condenser. Secondary and primary windings are wound together upon an air core. If an alternating emf of from 5000 to 10,000 volts is impressed upon the primary the condenser is charged until the voltage across the primary gap breaks it down. The condenser then discharges through the gap, producing an oscillating current in the primary winding. The oscillating current in the primary induces a high-frequency emf in the secondary, which is sufficient to break down the long secondary spark gap.

MEASUREMENTS AND MEASURING APPARATUS

By H. B. Brooks

1. STANDARDS

In the measurement of electrical, magnetic, thermal, and optical quantities, reference must ultimately be made to established units and verified standards. Experience has indicated the most suitable units and standards and also the most practicable procedures for carrying out the precise laboratory measurements upon which rest the less accurate but indispensable practical measurements.

DISTINCTION BETWEEN UNITS AND STANDARDS. The distinction between unit and standard should be carefully noted. A **unit** is a quantity in terms of which similar quantities are to be measured; a **standard** is a physical structure by which the unit is realized and made available. For example, the unit of electromotive force, the volt, is an invisible, intangible quantity, the very nature of which is unknown; but the **standard** of electromotive force is a particular kind of physical structure known as a standard cell.

The so-called "international" electrical units now (1936) in use will probably be replaced within a few years by those decimal multiples of the cgs electromagnetic units which the international units were originally intended to represent.

BASIC STANDARDS FOR ELECTRICAL MEASUREMENTS. All measurements of electric current, voltage, power, and energy, in either d-c or a-c circuits, are ultimately referred to resistance standards, standard cells, and time standards. Standards of mass (standard "weights") require some form of balance for their comparison. Similarly, the Wheatstone bridge and other bridges are used in the comparison of resistance standards, and potentiometers serve to measure electromotive forces in terms of the known electromotive force of a standard cell. In the use of bridges and potentiometers, adjustments are made in one or more arms of a network of conductors until a particular condition of balance is established, as shown by a suitable detector, usually by a galvanometer.

2. GALVANOMETERS

A galvanometer is an instrument for measuring a small electric current. A d-c galvanometer consists essentially of a permanent magnet and a coil or wire through which the current may flow. In the **moving-magnet galvanometer** the coil is fixed and relatively large; the magnet is very small and light and is suspended within the magnetic field of the coil so that it may readily turn as a result of the interaction of the field of the magnet and that of the coil. In the **moving-coil galvanometer** (often called d'Arsonval galvanometer) the coil is very light and is arranged to rotate within the field of the relatively large fixed permanent magnet. The **string galvanometer** is a variant of the moving-coil galvanometer, and has a conducting "string" (wire or metal-coated fiber) stretched within the field of a strong magnet. The string is deflected laterally when a current flows through it. (See article on Oscillographs.) In all forms of galvanometer the motion is opposed and brought to rest by a counter torque (or counter force, in the string galvanometer), by electromagnetic damping, and by friction. The last is made up of air friction, molecular friction due to imperfect elasticity of the suspensions or control springs, and (in pivoted galvanometers) of bearing friction.

MOVING-MAGNET GALVANOMETERS have certain advantages over moving-coil galvanometers which cause them to be used for some purposes in spite of their inherent disadvantages. Their advantages are (*a*) lightness of the moving element; (*b*) absence of current in the moving element, permitting the use of very delicate suspensions which (like silk and quartz fibers) may be non-conducting; (*c*) very high sensitivity as a result of (*a*) and (*b*); (*d*) the sensitivity may be changed by regrouping sections of the fixed coil, as well as by varying the degree of astaticism of astatic galvanometers; (*e*) the damping is virtually unaffected by changes in resistance of the external circuit. Their disadvantages are (*a*) great susceptibility to disturbance by variations of the local magnetic

field; (b) the damping is not as readily controlled as in the moving-coil galvanometer. Disturbances resulting from variation of the local magnetic field are reduced either by using an astatic construction or by surrounding the galvanometer with an iron shield or a number of concentric shields, or by both precautions. In the **astatic galvanometer** the moving system is a double one with magnetic polarities arranged in such a way that the moving system would be unaffected by a change in the strength of the local magnetic field, provided this change were such as to affect both elements of the astatic system equally. In practice such an ideal condition is seldom realized, and the user of astatic galvanometers (or other nominally astatic instruments) should take all reasonable care to avoid exposing them to stray magnetic fields.

MOVING-COIL GALVANOMETERS. Originally much inferior to moving-magnet galvanometers in sensitivity, moving-coil galvanometers have been refined and improved until they now serve for all but extreme requirements. They have the great advantages of being almost completely unaffected by even large variations in the local magnetic field, and of being readily damped by proper choice and adjustment of external circuit conditions. In some forms the damping may be regulated by a magnetic shunt.

MOTION OF GALVANOMETER MOVING ELEMENT. If the moving coil (or moving magnet) of a galvanometer be deflected from its zero position and then released, it may come to rest at the zero position only after one or more swings through this position. For this case the motion is said to be **periodic.** Under other conditions, the coil or magnet will return to its equilibrium position without passing through it. This constitutes **aperiodic** motion. When the damping is just sufficient to make the motion aperiodic, the galvanometer is said to be **critically damped.** In this condition the time required to come to apparent rest is a minimum. When critically damped, the moving system will reach its final deflected position, within 0.1 per cent of the deflection, in about 1.5 times the free period. Theoretically this is the ideal condition of operation, but a slight amount of underdamping is usually preferable because it allows the coil to overshoot the rest position slightly and then return to it. This gives assurance that sticking is not present.

The **damping ratio** of a galvanometer is the ratio, expressed as a positive number, of a given deflection to the next deflection in the opposite direction. The greater this ratio, the greater the degree of damping. The natural logarithm of this ratio is called the **logarithmic decrement.**

Much time will be lost, in using moving-coil galvanometers, if the total resistance in the galvanometer circuit is widely different from the value which gives aperiodic motion. If one is constrained to choose between using a galvanometer in a circuit having (for example) only one-half the resistance for critical damping, or in a circuit of twice the critical value, the latter condition, giving underdamping, is preferable to the former because with it the moving system comes to apparent rest in a shorter time.

SENSITIVITY OF GALVANOMETERS. The sensitivity of a galvanometer may be defined either as its response (in specified deflection units) to unit stimulus, or as the magnitude of the stimulus required to produce a specified unit deflection. The second form of definition gives a numerical value of sensitivity (for a given galvanometer) which is the reciprocal of the value given by the first definition. For example, the sensitivity of a given galvanometer may be stated either as 10 mm per microvolt, or as 0.1 microvolt per mm. Both systems of definition are in successful use, and the ease with which the sensitivity may be translated from one form to the other evidently explains the lack of confusion which would ordinarily attend the use of radically different definitions for the same thing.

The second form of definition has been found more convenient in American manufacturing practice. In galvanometers having attached scales the specified unit deflection is assumed to be one scale division. In reflecting galvanometers for use with separate reading devices the standard unit deflection is assumed to be 1 mm, with a scale distance of 1 meter. The **current sensitivity** is usually expressed as the number of microamperes to produce the specified unit deflection. The **voltage sensitivity** is expressed as the number of microvolts that must be impressed on the circuit consisting of the galvanometer coil and the external resistance for critical damping to produce the specified unit deflection.

The **ballistic sensitivity** is expressed as the number of microcoulombs which must be discharged through the galvanometer to produce the specified unit deflection. The **megohm sensitivity** is expressed as the number of megohms in the galvanometer circuit for which an impressed emf of 1 volt gives the specified unit deflection.

Particular care is necessary in making and in interpreting statements concerning the microvolt sensitivity of galvanometers, because some makers state the microvolt sensitivity as the microvolts per millimeter (or reciprocally, as the millimeters per microvolt) at the galvanometer terminals. Most modern moving-coil galvanometers are so

designed that they cannot be effectively used with the zero value of external resistance implied in this definition, because this condition causes excessive overdamping. All statements of microvolt sensitivity should contain definite information as to the total resistance to which they refer. When such a statement is not given in the maker's catalog, his basis for the definition of microvolt sensitivity can often be discovered from other data given, namely, the microampere sensitivity and the resistance of the galvanometer. A statement of the external resistance for critical damping should always be included in makers' statements concerning their moving-coil galvanometers.

The use of the above-defined second method of stating sensitivity gives numerical values (for galvanometers of relatively high sensitivity) in the form of very small decimal fractions. To avoid this, some foreign makers who follow this principle in defining sensitivity use units of current and voltage smaller than the microampere and microvolt respectively. For example, in a single circular of one maker the current sensitivity of various galvanometers is given in terms of 10^{-7}, 10^{-8}, 10^{-9} and 10^{-10} amp, and the voltage sensitivity is given in millimeters for 10^{-8} volt. This lack of uniformity in the units used in stating galvanometer sensitivity would be a source of inconvenience to the user if it were not so easy to convert a given sensitivity from one form to another. The need for a named unit of current smaller than the microampere (and continuing the sequence, ampere, milliampere, microampere) has induced some foreign authors to use the word **nanoampere** to signify 10^{-9} amp.

The attempt is sometimes made to increase the effective sensitivity of a galvanometer by placing the scale at a comparatively great distance from it. In doing this, some users overlook the fact that the instability of the zero is magnified in the same ratio as the deflections. The use of an increased scale distance is justifiable only when the stability, including the effect of vibrations, is in excess of the precision of reading.

GALVANOMETER SHUNTS. For many purposes it is essential to reduce the sensitivity of a galvanometer to a definite fraction of its value. This is conveniently done by connecting a resistance across the galvanometer terminals to bypass the greater part of the current. If the resistance of this bypass ("galvanometer shunt") is $^1/_9$, $^1/_{99}$, or $^1/_{999}$ of the galvanometer resistance, the current sensitivity will thereby be reduced to $^1/_{10}$, $^1/_{100}$, or $^1/_{1000}$ of its original value, respectively. A simple shunt of this sort has two drawbacks, namely, it must be adjusted for a particular galvanometer, and unless it is wound with copper wire it will not have the correct shunting effect except at some one temperature. To overcome these defects, the Ayrton-Mather shunt was designed. See Fig. 1. It may be shown that if the combination of galvanometer and shunt has a given value of current sensitivity with the slider on the stud b, the current sensitivity with the slider on any other stud x will be lower in the ratio of r to R, regardless of the resistance of the galvanometer. In choosing an Ayrton-Mather shunt for a moving-coil galvanometer the value of R should be selected with reference to the external critical damping resistance and the probable value of resistance of the circuit to be connected to the terminals A and B so that the damping will be satisfactory.

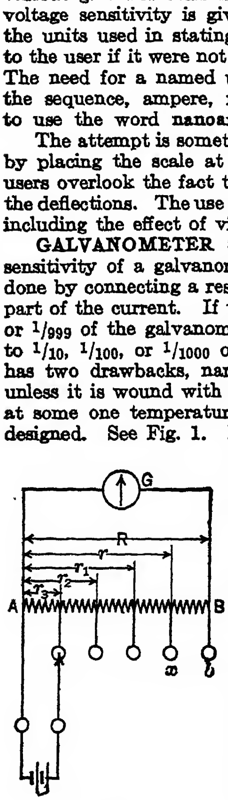

FIG. 1

The Ayrton-Mather shunt was originally devised for use in circuits of high resistance, such as were encountered in measurements of insulation resistance. When this shunt is used in such a circuit the variations of resistance produced by the operation of its range-changing switch have an inappreciable effect on the magnitude of the current in the external circuit. However, when the Ayrton-Mather shunt is used with the low-resistance external circuits so common at this time, large variations in the current in the external circuit may be caused by changing the range of the shunt. While a compensating resistance could be used, it is often preferable and less expensive to use an ordinary galvanometer shunt.

CHOICE OF A TYPE OF GALVANOMETER. A moving-coil galvanometer should always be preferred to a moving-magnet galvanometer except for some very special purposes. For any application the most robust, simple, and inexpensive galvanometer which has sufficient sensitivity with a suitable period should be chosen. In general, superfluous sensitivity increases the first cost of the galvanometer and tends toward greater delicacy and hence fragility, as well as toward a longer period and consequently greater time required for observations. For the most precise work of the standardizing laboratory it is necessary to use delicate, expensive galvanometers of relatively long period and to employ a reading arrangement consisting of a telescope and scale or a lamp

and scale. Such moving-coil galvanometers are made in this country in two grades of sensitivity and at corresponding prices. For work requiring only moderate sensitivity, with shorter periods, portable lamp-and-scale galvanometers are supplied as compact, self-contained units. For work requiring still lower sensitivity, robust portable suspended-coil pointer galvanometers are available having the advantages of low price and ease of exchange or replacement of the coil system. For some purposes for which moderate sensitivity is sufficient and the deflection should be proportional to the current over a relatively large angle, pivoted pointer galvanometers are made which embody the standard features of construction of d-c indicating instruments.

Certain old theorems state that for maximum sensitivity the coil of the galvanometer should be wound to have a resistance equal to the "internal resistance" of the source of the emf which is to produce the deflection. Although this can be proved to be true as a matter of mathematics, the statement is largely of academic interest, as one can depart very widely from the theoretically correct value of coil resistance with but little loss of sensitivity. Furthermore, most moving-coil galvanometers as now made are designed to be used with an external resistance of, say, 3 to 15 times the coil resistance in order to get suitably damped motion. (This statement does not apply to galvanometers having damping frames or damping windings to increase still further the value of external resistance for critical damping.) A more practical rule for choosing a moving-coil galvanometer is as follows: If a given small emf in an external circuit of resistance R is to be detected or measured, select the galvanometer which has a value of external critical damping resistance most nearly equal to R; if no available galvanometer has just this value, select the galvanometer for which the external resistance for critical damping falls short of R by the smallest amount. The resulting motion will be underdamped, which is much to be preferred to overdamping; if desired, the damping may be improved by suitably shunting the galvanometer.

PARASITIC THERMAL EMF IN GALVANOMETERS. Moving-coil galvanometers as made without special precautions against parasitic emf contain a number of junctions of dissimilar metals. The resultant thermal emf will depend upon thermal conditions, and may amount to 10 or 20 microvolts under very bad conditions, for example, in winter weather when a descending current of cold air strikes the top of a galvanometer but does not sensibly affect the temperature of the bottom. Older forms of galvanometers with a long tube at the top containing the suspension are particularly liable to this defect, which is of consequence chiefly when relatively low voltages are to be detected or measured by the galvanometer. The thermal emf may be minimized by enclosing the galvanometer in a case made (*a*) of metal, such as copper, aluminum, or brass, of high thermal conductivity; or (*b*) of material of high thermal resistivity (cork, balsa wood, etc.). In (*a*) the metal enclosure will have nearly the same temperature in all its parts; in (*b*) the galvanometer itself, protected from radiation and convection, will have a nearly uniform temperature in all its parts. Some makers supply galvanometers in which not only the coil but also the suspensions, binding posts, etc., are made of copper to minimize thermal emf. It is important that ballistic galvanometers should be so constructed.

BALLISTIC GALVANOMETERS. Ballistic galvanometers are used to measure a quantity of electricity, such as is given up by a condenser during discharge. They are usually constructed to have a relatively long period for one or both of the following reasons: first, because a longer period makes it easier to read the momentary maximum deflection; second, because in some applications the time required for the passage of the electrical quantity is relatively great enough to introduce an error if a galvanometer of short period should be used.

Ballistic galvanometers may be used either undamped or damped. When critically damped they have only about one-third the sensitivity when undamped, but for most applications the sensitivity is so ample that the reduction which accompanies critical damping can well be tolerated for the sake of the much greater convenience in operation.

The **ballistic constant** of a galvanometer is conveniently expressed as the number of microcoulombs per millimeter deflection with a scale distance of 1 meter. It is usually determined by discharging through the moving coil a known quantity of electricity from a charged condenser or from the secondary winding of a mutual inductor. In the former case the quantity in microcoulombs is the product of the capacitance of the condenser in microfarads and the difference of potential in volts to which it is charged. Ballistic galvanometers have important applications in magnetic testing. For a discussion of their use in this field, and the method of calibrating them by means of a mutual inductor, see Testing of Magnetic Materials.

A-C GALVANOMETERS. The two forms of a-c galvanometer most used in this country are the vibration galvanometer and the moving-coil separately excited galva-

nometer. In its usual form, the moving-coil vibration galvanometer differs from the d-c moving-coil galvanometer chiefly in having a very narrow coil and stiff suspensions. The stiffness of the suspensions is adjustable to bring the natural frequency of the moving system into resonance with the frequency of the a-c supply circuit. For any other frequency the sensitivity is relatively very small, and harmonics present in the wave form are substantially without effect on the deflection. This valuable property of the vibration galvanometer often makes possible the use of the simple mathematical relations based on the assumption of a sine-wave form, even though the available a-c supply voltage contains harmonics.

The moving-coil separately excited a-c galvanometer differs from the ordinary d-c moving-coil galvanometer mainly in having a laminated electromagnet and a laminated core in place of a permanent magnet and solid core. The theory of this class of galvanometer has been thoroughly treated by Weibel; see Bibliography. Unlike the vibration galvanometer, the separately excited a-c galvanometer is not restricted to a particular frequency (or frequency range). It must be excited by a current of the same frequency as that used in the measurement circuit (bridge or potentiometer). It responds only to that component of the current in its moving coil which is in time phase with the magnetic flux in which the coil is located, and consequently for maximum sensitivity the current in the coil must be in phase with the flux. It is also possible to overload and damage the coil without producing a large deflection, if the current is nearly in quadrature with the flux. In some cases the in-phase condition of current and flux is readily and simply attained; for example, in using the galvanometer with a resistance bridge, the exciting coil of the galvanometer is connected to the supply circuit through a suitable non-inductive resistance, and the current for the bridge is taken from potential taps on this resistance. To obtain proper damping in reflecting galvanometers of this type, the circuit external to the galvanometer must have suitable values of resistance, inductance, and capacitance. When these conditions are fulfilled, the separately excited a-c galvanometer has a possible sensitivity but little inferior to that of d-c moving-coil galvanometers of corresponding construction. In the use of the robust pointer-type a-c galvanometers no particular attention has to be paid to the external inductance and capacitance in order to obtain good damping in the usual circuits.

SUPPORTS FOR GALVANOMETERS. Sensitive reflecting galvanometers should preferably be mounted on stable masonry walls or piers free from vibration. Vibration galvanometers are particularly susceptible to mechanical vibrations set up in buildings by the operation of motors or alternators at the frequency for which the galvanometers are tuned. When trouble is experienced with either d-c or a-c galvanometers mounted on the best available firm supports, recourse must be had to expedients, of which the Julius suspension is among the oldest. See bibliography, paper by W. P. White in *Phys. Rev.*, 1904, vol. 19, p. 323, and book by Werner. At the Bureau of Standards, vibration galvanometers are protected as follows: A slab of concrete weighing about 400 lb is supported by four helical steel springs. On top of the slab is a layer of hair felt 1.5 in. thick on which is a board upon which the galvanometers are placed. This spring-supported slab is a vibrating system with a natural period so great in proportion to the period of the galvanometer system that it has no tendency to pick up vibrations of the frequency of the galvanometer system. The felt pad is effective in damping out vibrations of higher frequency which may be transmitted along the length of the steel wires composing the helical springs. Hartsough (see Bibliography) has stated that the shielding of a sensitive apparatus from vibration is very nearly perfect when it is supported on thin inflated rubber bags. In his work three interconnected bags were used, containing air at a pressure of about 50 cm (20 in.) of water, and a mass of about 4 lb was placed on each bag.

3. STANDARD CELLS

These are primary cells made of pure materials in accordance with exact specifications. They have the special characteristic of maintaining a very constant emf when suitably cared for and used. They are of great and increasing importance as standards of emf.

The only kinds of standard cell of technical importance at present are the **saturated cadmium cell** called by international agreement the "Weston Normal Cell," which serves as the primary standard of emf in national and other important standardizing laboratories, and the **unsaturated cadmium cell** which is used generally (except in England) in engineering laboratories and industrial plants as a secondary or working standard of emf.

WESTON NORMAL CELL. Fig. 2 shows the construction of this cell. The H-form glass vessel, with a platinum lead-in wire at the bottom of each limb, contains mercury covered with mercurous sulfate paste as the depolarizer in the positive limb, cadmium

amalgam in the negative limb, and cadmium sulfate solution with an excess of cadmium sulfate crystals above the paste and amalgam as shown. For the exceedingly exact work for which these cells are used, they must be kept at a very constant temperature. In the standard-cell laboratory of the National Bureau of Standards the normal cells are kept in baths of oil maintained very accurately at 28 deg cent by a sensitive thermostat. The choice of this temperature was made because of climatic conditions in Washington, in order to avoid the condensation of moisture from the air upon parts of the oil bath in humid summer weather. Aside from such considerations, other temperatures would be equally suitable. The normal cells of England, France, and Germany are kept at about 20 deg cent.

For very exact work the saturated cells should be maintained at as near a constant temperature as practicable for at least several days before electrical comparisons are made, because, in addition to having an appreciable temperature coefficient, these cells do not immediately assume their true emf after a change in temperature.

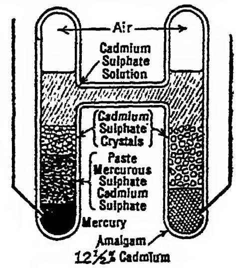

FIG. 2

UNSATURATED CADMIUM CELL. This cell differs from the normal cell in having no excess crystals of cadmium sulfate. The concentration of the cadmium-sulfate solution is intended to be such that it will reach saturation when the temperature is reduced to approximately 4 deg cent, a feature which insures a minimum effective temperature coefficient of the cell within the temperature range permissible in normal use. The unsaturated cell also differs from the normal cell shown in Fig. 2 in being made portable by the use of some form of porous plug or septum above the active material in each limb to keep these materials in place even when the cell is inverted.

CHARACTERISTICS OF THE TWO KINDS OF CELL. The Weston Normal (saturated) Cell, made to specifications from carefully purified materials, has a highly reproducible value of emf which usually remains very constant for years if the cell receives proper care. It has, however, an appreciable temperature coefficient of emf. The unsaturated cell is not as reproducible in emf, and there is usually a slow decrease of emf with time. Only very general statements may be made in regard to the rate of decrease of emf. Some very exceptional unsaturated cells have decreased over a long period of years by only 10 to 15 microvolts per year. A decrease of 25 to 50 microvolts per year may be taken as average performance. Some cells have shown a decrease of 100 microvolts per year. Any rate of decrease much in excess of this figure may be taken as an indication of either abuse of the cell or defect in materials or workmanship.

The advantages of the unsaturated cadmium cell are its portability and the very low temperature coefficient of cells which are within certain limits of emf. To be acceptable, new cells should have values of emf within the range 1.0185 to 1.0195 international volts; such cells have extremely small temperature coefficients provided all parts of the cell are at the same temperature and no abrupt changes of temperature have recently occurred. However, as the emf of the cell decreases with age and use, an appreciable temperature coefficient of emf develops. The National Bureau of Standards does not issue certificates for cells having an emf lower than 1.0180 international volts. For very accurate work it is advisable to use cells for which the emf is not lower than 1.0183 international volts. (At the time this is being written, it seems evident that the arbitrary international electrical units will be replaced, possibly by the year 1940, by the absolute electrical units. The present international volt is approximately 0.0004 volt larger than the "absolute volt" equal to 10^8 cgs electromagnetic units of emf. After the absolute units are adopted, the numerical values of emf given in this paragraph should be increased by 4 units in the fourth decimal place.)

It is important to realize that the low temperature coefficient of the unsaturated cadmium cell is actually the small difference between two relatively large temperature coefficients of opposite signs (those of the two limbs), and consequently depends upon the existence of a high degree of temperature equality between the two limbs.

MEASUREMENT OF EMF OF STANDARD CELLS. The emf of a standard cell is measured by comparing it with that of another cell, the "reference cell," which is taken as a basis. In national standardizing laboratories the reference cell is compared at suitable intervals with the cells composing the primary standards of the institution. In industrial and engineering laboratories which do not maintain a group of Weston normal (saturated) cells, the reference cell is one for which the emf has been certified by a standardizing laboratory.

Standard cells must be measured by the null (potentiometer) method to avoid taking

any current from them. Although it is possible to measure the entire emf of the cell under test with a potentiometer, the opposition method is much more accurate and can be carried out with a very much simpler and inherently less accurate potentiometer. In the opposition method the emf of the cell under test is opposed to that of the reference cell and their small difference is measured with a potentiometer. Attention must be paid to the algebraic sign of this difference, so that its numerical value may be added to, or subtracted from, the value of the emf of the reference cell to obtain that of the cell under test.

INTERNAL RESISTANCE OF STANDARD CELLS. The internal resistance of the normal (saturated) cell, of the usual construction and in good condition, may be taken as from 600 to 800 ohms. The internal resistance of the portable (unsaturated) cell, when made up in glass vessels of the size used by the principal national standardizing laboratories for normal cells, is about 500 ohms. For some purposes, particularly for use with a deflection potentiometer, this high value of resistance is a drawback. One American manufacturer regularly supplies portable cells with an internal resistance of about 100 ohms, while another maker supplies two forms having nominal internal resistances of 500 ohms and 100 ohms, respectively. Cells having the latter value are particularly desirable for use with the deflection potentiometer.

To measure the internal resistance of a standard cell, first measure its emf in terms of that of any other cell used as a reference cell in the manner above described, then shunt the cell under test with a resistance of 1 megohm and note the resulting apparent decrease in emf. The numerical value of this decrease, expressed in microvolts, is (with sufficient accuracy) the numerical value of the internal resistance in ohms. The current through the 1-megohm resistor should be allowed to flow only long enough to obtain the reading. This resistor should be of the wire-wound type.

HIGH RESISTANCE RESULTING FROM GAS BUBBLE. In time, a gas bubble may form between the amalgam and the septum of a portable cell. Though harmless at first, the bubble may grow until it has forced out the solution between the amalgam and the septum and thereby open-circuited the cell. Before this extreme condition is reached, the internal resistance increases sufficiently to impair the usefulness of the cell by reducing the working sensitivity of the galvanometer through which the emf of the cell is opposed to some other emf or potential difference.

If periodic measurements of the internal resistance of a cell show increasing values which are variable through rather wide limits, depending upon whether the cell is in the normal upright position or slightly inclined, the existence of a gas bubble at the amalgam limb is indicated. This test may be applied without the necessity of breaking the maker's seals.

PRECAUTIONS IN USING STANDARD CELLS. No appreciable current can be taken from a standard cell without some alteration of its emf. If the current is small and flows for only a short time, the change is not permanent, and the cell gradually recovers its original emf; of course the cell is unreliable until the recovery is complete. Consequently, standard cells should be used only in methods in which their emf is opposed to an equal emf, as in connection with potentiometers. They should always be protected by a key or set of keys, which are closed only momentarily, and for preliminary adjustments a resistance of at least several thousand ohms should be in series with the cell. When an approximate balance has been obtained this resistance may be cut out and the final balance then made.

In using portable standard cells, care should be taken to protect them from drafts of air, from sunlight, and from heat radiation from lamps, rheostats, radiators, steam pipes, etc., to prevent unequal heating of the two limbs of the cell. Even the heat of the hand, applied for several minutes, may so unbalance the temperature as to produce a noticeable change in the emf. The magnitude of this change, for various kinds of temperature disturbance which might occur in practice, has been determined by J. H. Park (see Bibliography). Cells may be protected by a thick wrapping of felt or other heat-insulating material. In the electrical instrument laboratory of the National Bureau of Standards each cell is kept in a thick-walled copper pot jacketed with heat-insulating material. Such precautions are justified when one wishes to avoid errors of the order of 0.01 per cent, as is necessary when acceptance tests are made on instruments with a guaranteed accuracy of 0.1 per cent.

At least three portable standard cells should be provided for a laboratory having a single potentiometer. The cells should be intercompared at least once a month; oftener if they are frequently used. A change of emf of one of the cells, from improper handling or other cause, will be revealed by its failure to check with the other two.

It is preferable not to ship standard cells in extremely cold weather, although when the cells are properly packed instances of damage from exposure to low temperatures

during shipment seem to be infrequent. It is much more objectionable to *carry* the cells from place to place in cold weather, either without packing or so insufficiently packed as to afford little protection from the cold. After exposure to temperatures outside the permissible range (4 to 40 deg cent; that is, 39 to 104 deg fahr) the cell may recover its normal emf after a rest of, say, several weeks at a reasonably constant temperature within the permissible range.

A standard cell should never be connected to a voltmeter in the attempt to measure its emf or to check the reading of the voltmeter. The voltmeter reading will be lower than the emf of the cell by an indeterminate amount, and unless the voltmeter be of relatively high resistance the emf of the cell will be altered, at least for a time.

4. TIME STANDARDS

Time enters into electrical measurements in passing from the measurement of power (rate of flow of energy) to the measurement of energy itself. Time also enters in a-c measurements; for example, the frequency of an alternating voltage or current is the reciprocal of the time required for a complete cycle. Time measurements in the laboratory cover an extremely wide range as to the magnitude of the time, the accuracy required, and the time-measuring devices available for various purposes. Among these may be mentioned clocks, stop-watches, synchronous timers, tuning forks, and piezoelectric oscillators, the last-named being capable of an accuracy which threatens to expose some of the failings of the most accurate astronomical clocks.

For the measurement of time in the testing of portable standard watthour meters stop-watches are often used. In the effort to avoid some of the errors of the stop-watch, special devices have been developed by meter engineers which make use of pendulum clocks which are in turn checked against radio time signals from Arlington. These have been described in the Reports of the N.E.L.A. Meter Committee.

5. RESISTANCE STANDARDS

MAINTENANCE OF THE OHM.—Although a specified column of pure mercury (the "mercury ohm") has been involved for many years in the laws of many civilized nations as the ultimate material standard of electrical resistance, the national standards laboratories have found it impracticable to maintain the unit of resistance by frequent reference to it, and instead, have maintained the international ohm largely by reference to the mean value of selected manganin coils. The German Reichsanstalt has used the same four 1-ohm coils since 1892 for this purpose. The National Bureau of Standards has maintained its unit of resistance since about 1910 by the use of ten 1-ohm manganin coils, selected for constancy from a larger group. From time to time, however, any of the ten coils which have not maintained their values with a satisfactory degree of constancy have been replaced by others chosen from the larger group.

At its meeting in Paris in 1930, the (international) Advisory Committee on Electricity recommended to the International Committee of Weights and Measures that no further mercury-ohm determinations should be made. The General Conference of Weights and Measures of 1933 approved in principle the abandonment of the present "international" ohm, volt, and ampere, with their arbitrary definitions in terms of mercury and silver, in favor of the absolute ohm, volt, and ampere, equal to 10^9, 10^8, and 10^{-1} of the corresponding cgs electromagnetic units. It appears evident that this step will be taken within the decade 1930-1940. The "international" ohm is larger than the absolute ohm by about 0.05 per cent; the international ampere is about 0.01 per cent smaller than the absolute ampere; and the international volt about 0.04 per cent larger than the absolute volt.

Absolute measurements of resistance will soon form the ultimate basis of reference by the national laboratories, but for years to come the maintenance standards of resistance will continue to be coils of wire of low temperature coefficient. Although better alloys are hoped for and sought after, manganin has for many years been virtually the only resistance alloy used for the "wire standards," not only for the reference coils just mentioned, but also for working standards of all degrees of importance and accuracy.

FORMS OF CONSTRUCTION OF RESISTANCE STANDARDS. These standards, for resistances of 0.1 ohm and above, are usually wound with manganin wire, and for the most accurate work are designed for immersion in an oil bath or contain oil, surrounding the coil, in a sealed case. They are generally provided with copper terminals for immersion in mercury cups formed in copper connection blocks. In the older Reichs-

anstalt type (Fig. 3) the distance between centers of the copper terminals is 160 mm (6.3 in.), and the case is perforated to permit the oil of the bath to circulate around the coil. In the type developed at the National Bureau of Standards by E. B. Rosa (Fig. 4), the case contains purified oil and is hermetically sealed to prevent the entrance of moisture. The distance between the centers of the terminals of the Rosa-type coil is 75 mm (3.0 in.). In the more recent resistance standard devised by J. L. Thomas at the National Bureau of Standards (see Fig. 5), the general dimensions and the distance between centers of terminals are the same as in the Reichsanstalt type, but the coil is hermetically sealed in the space between two coaxial brass tubes; it is wound on (and hence in good thermal contact with) the inner tube, which is in contact with the oil of the bath. The manganin wire is thus protected from chemical attack which might occur if the oil should deteriorate. The wire of the Thomas standard is annealed at a red heat after winding, and is not

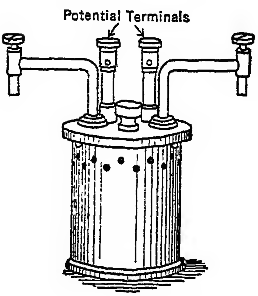

Fig. 3

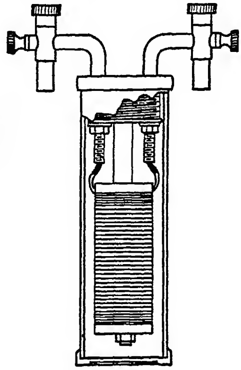

Fig. 4

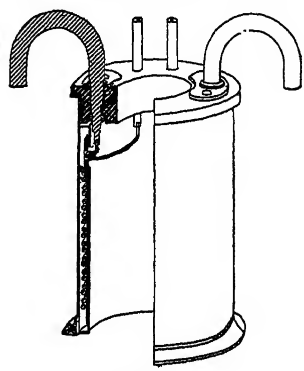

Fig. 5

bent or otherwise deformed after this annealing. Coils of the Rosa type and the Thomas type are exempt from change of resistance which occurs in unsealed coils as a result of variation of atmospheric humidity.

Resistance standards of values lower than 0.1 ohm are usually made of manganin sheets hard-soldered to copper terminals, and are of the four-terminal type to avoid contact-resistance errors at the terminals; that is, the resistance is adjusted to a stated value between two potential terminals which are connected to points on the resistor intermediate between those at which the current enters and leaves the standard. These standards, when used with a potentiometer for the measurement of current, are often colloquially called "shunts" because of their similarity to ammeter shunts.

AIR-COOLED VS. OIL-COOLED RESISTANCE STANDARDS. For a given difference of potential at rated current the power loss (and hence the rate of liberation of heat) increases with the current. Some forms of resistance standard for large currents are made for oil immersion, the oil being cooled by circulating water. Other forms are designed primarily for use in still air. To avoid excessive weight and cost, standards of the latter type are made with progressively lower values of potential difference as the rating in amperes increases. Oil-immersed heavy-current standards may have a larger value of this potential difference, with which certain sources of error (such as thermal emf) have correspondingly less effect on the accuracy of the measurements. The use of oil makes it possible to determine the temperature of the manganin more accurately. These advantages are accompanied by the usual disadvantages of oil immersion, among which are the necessity for providing for cooling water; the possibility of leakage or creeping of oil; the tendency for oil to become rancid in time and to attack the manganin. Both oil-cooled and air-cooled standards for large currents are used, according to the properties upon which the user lays the most emphasis. Air-cooled standards may on occasion be used in oil, or in a forced current of air. The Bureau of Standards uses non-inductive resistance standards, cooled by a forced air current, in testing current transformers up to 500 amp. Beyond this value it is necessary to resort to oil cooling to obtain an adequate voltage drop with a sufficiently low temperature rise and suitable dimensions.

LIMIT OF ERROR AND RATED CURRENT OF RESISTANCE STANDARDS. Single-value standards of 1 ohm or decimal multiples of this value, not exceeding 10,000

ohms, are usually adjusted to a stated limit of error of 0.01 per cent when used with a current corresponding to 0.1 watt loss. For 0.1 ohm and lower decimal submultiples of the ohm, the stated limit is generally 0.02 per cent, but this figure refers to a current corresponding to 1 watt loss. Standards of 1 ohm and above may be used with a load of 1 watt, and those of 0.1 ohm and below with 10 watts, with reduced accuracy during use but without any permanent change in resistance as a result of the load. The statements in this paragraph apply to standards having terminals for mercury-cup connections, and used in an oil bath.

Resistance standards ("shunts") of 0.1 to 0.00001 ohm, for measuring large currents, have various values of permissible power loss. The user should obtain information on this point from the maker, or from experiments to show the temperature rise of the manganin and the consequent change in the resistance of the standard.

6. RESISTANCE BOXES

CONSTRUCTION OF RESISTORS. A resistance box or precision rheostat is a group of resistors assembled in a case and provided with means for varying the resistance in circuit between two terminals. The resistors are usually of manganin wire and differ from those used in the best grade of resistance standards chiefly in being of smaller dimensions and lower accuracy of adjustment. It is standard practice to wind the resistors noninductively. For use with direct current, and with alternating current of usual power frequencies, the ordinary bifilar winding is usually satisfactory. Its use results in a coil having a time-constant nearly equal to zero, for coils of 100 ohms: for lower values the inductance predominates, for higher values the coil behaves like a pure resistance shunted by a capacitance. The bifilar winding is objectionable for coils of high resistance (1000 ohms and above) when used with frequencies above those for power and lighting, and various special types of winding have been devised to minimize both inductance and capacitance. The greatly increased use of frequencies in the audio range and higher has stimulated the development of resistors and boxes of very low time-constant; for example, a recent line of resistance boxes by Leeds & Northrup Co. is stated to have a time-constant of less than 0.1 microsecond for all settings above 5 ohms.

The coils of resistance boxes are usually wound on spools of wood, brass, porcelain, lava, or molded insulating material. In some cases the wire is wound on cards of mica or other sheet insulating material, or woven, with threads of silk or other insulating materials, to form a fabric. These constructions give a very low time-constant and good facility for the escape of heat from the winding.

ARRANGEMENT OF RESISTORS. The resistance between the terminals of a resistance box is varied by changing the manner of connection of its resistors, either by shifting plugs or by turning rotary switches. The 1, 2, 3, 4 and the 1, 2, 2, 5 plug arrangements are the most usual. Using the former, a resistance box of 1110 ohms total would contain resistors of the following resistances: 1, 2, 3, 4, 10, 20, 30, 40, 100, 200, 300, 400 ohms. The resistors are in series between the terminals, and the junctions of adjacent coils are connected to brass blocks which are reamed to receive taper plugs between them. See Fig. 6. The insertion of a plug short-circuits a resistor. The disadvantages of these arrangements are the time and mental effort required to add up the values of the resistors unplugged, the likelihood of errors, and the risk of loss of plugs. A further disadvantage of this construction is that there are a maximum number of plug contacts in circuit when the resistance setting is a minimum. Thus the lower the resistance setting the greater the likelihood of error or variability of resistance arising from imperfect contacts at the plugs. The decade form of plug resistance box avoids all these disadvantages except the risk of loss of plugs; the amount of resistance in circuit can be read off directly from the position of a single plug in each decade; the decade plan is usually preferred. While the original decade arrangements had 9 (or 10) resistors per decade, special arrangements have been devised to obtain 9 (or 10) steps with a smaller number of resistors. The object is to reduce the cost of the box for a given total resistance. Among these arrangements may be mentioned Northrup's, using coils of 1, 2, 3, and 3 units; Smith's, using coils of 1, 2, 2, 2, and 2 units; these and other arrangements are discussed by Northrup; see book section of Bibliography. When some of these plans are used with the rotary-switch construction the resistance of the decade goes through some undesired value as the brush passes from one stud to the adjacent one. Behr's new arrangement for a 10-step decade, free from this disadvantage, con-

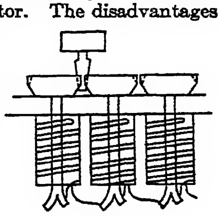

Fig. 6

sists of 6 resistors of 2 units each, two being connected in parallel when the resistance of the decade is to have an odd value.

PLUGS VS. SWITCH CONTACTS. Plug contacts, when carefully made, cared for and used, give (in general) a lower and more definite contact resistance than switch contacts. However, well-made switch contacts, when properly cared for, have a satisfactory definiteness of contact resistance and have the advantages of more rapid manipulation and reading, with no loose parts to be mislaid or lost. They require more care than plug contacts. Switch contacts are now generally preferred for most purposes. They permit placing all the live parts inside the box, and inside the metal shield in the case of shielded resistance boxes for a-c use. The location of the live parts where the operator cannot come in contact with them is an advantage when the box is used in a high-voltage circuit. For resistance boxes for use on high frequencies the switch construction makes it possible to keep the geometry of the internal circuit fixed. In the most recent boxes for this purpose the number of resistors in circuit is constant for all settings, even the connectors in the zero position being in effect resistors which are balanced as to resistance and inductance.

The angle of taper of the plug is an important detail. A taper of 1 in 12 is very satisfactory. Taper reamers having this angle ("1 in. per ft.") are supplied as standard articles by U. S. tool manufacturers. A taper of 1 in 10 is much used. If the taper of the plug is too pronounced, the plug is likely to loosen spontaneously; if the taper is much less pronounced than the above values, the lateral forces tending to spread the contact blocks apart will be excessive and the plug may seat so tightly as to require undue force for its removal.

MAINTENANCE OF CONTACTS. In both the plug and the switch constructions the contact surfaces must be kept clean and properly lubricated if the contact resistance is to be kept low and definite. It has been shown that the use of a suitable petroleum oil on these surfaces not only avoids cutting and scoring but also reduces the contact resistance and makes it more definite. The purified petroleum oils used internally in medicine (such as "Nujol") are very suitable. Keinath states that to give a satisfactory contact the force between the brush and the contact segment should be of the order of magnitude of 1 to 2 kg (2 to 4 lb), and that, to avoid the resulting danger of scoring, the contact surfaces should be kept greased with vaseline. The use of vaseline is satisfactory when the contacts are effectively protected from dust, but for open switch contacts vaseline becomes thickened by the dust and eventually makes the contact resistance high and irregular. When exposed contacts are lubricated with a suitable oil this difficulty does not arise.

It is an advantage to have the switches inclosed to hinder the access of dirt, but the construction should be such as to allow ready access for cleaning and oiling.

Further information applying to plug and switch contacts as used in resistance boxes is given in the section on Bridges under the heading Accuracy of Measurements with Wheatstone Bridge.

7. BRIDGES

GENERAL. Instruments embodying forms of networks known as **bridge circuits** are used for the measurement of resistance, inductance, capacitance, frequency, etc. The operation of a bridge consists in varying the constants of its component circuits or "arms" until the response of a suitable detector connected between two points on the network is reduced to zero or to an amount measurable by the detector for the purpose of interpolation.

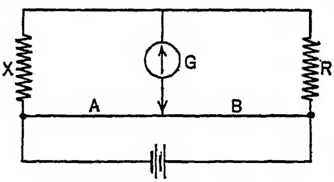

FIG. 7

SLIDE-WIRE BRIDGE (Fig. 7). This very simple form of bridge, of low cost and moderate accuracy, is identical in principle with the Wheatstone bridge (see below), the difference being that a simple wire AB forms the two ratio arms. It may be a wire of uniform resistance per unit length, stretched along a meter scale divided into millimeters. All connections in the X and R circuits are of low resistance. A slider is arranged to make contact at any desired point along the wire. When the bridge is balanced,

$$X = AR/(1000-A) \tag{1}$$

where A is the distance in millimeters between the slider and the left-hand end of the slide wire. The accuracy will be greater when the slider is nearer to the center of the wire. For this case the error may be minimized by taking the mean of two values of X,

between which the relative positions of X and R are interchanged. The accuracy may be increased by adding end coils to the slide wire, but at the expense of reduction of the range of measurement.

WHEATSTONE BRIDGE. Fig. 8 shows diagrammatically the arrangement of resistances in an ordinary Wheatstone bridge. A and B represent two coils or sets of

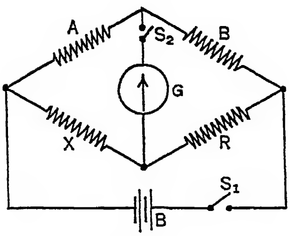

FIG. 8

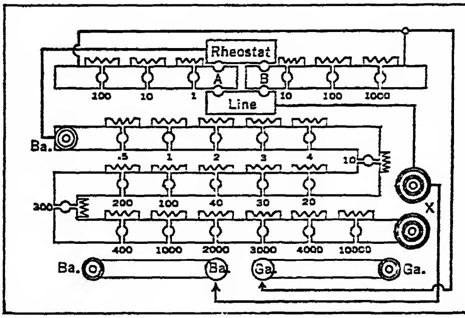

FIG. 9

coils, usually called the "ratio coils" or "ratio arms." Their relative resistances must be known but their absolute accuracy of adjustment is immaterial. R is usually a set of coils which can be connected to give any value of resistance, by small equal steps, from zero to the maximum; X is the unknown resistance, G a galvanometer connected in one diagonal of the bridge, and B the battery in the other diagonal. The operation of the bridge consists in successively adjusting R until the galvanometer shows no deflection, or until two values of R are found which differ by the smallest step and between which lies the value of R for no deflection, obtained by interpolation of the galvanometer deflections. The value of the unknown resistance is then

$$X = \frac{AR}{B} \tag{2}$$

where the letters represent the resistances of the four arms.

Forms of Wheatstone Bridge. Wheatstone bridges are made in a variety of forms, sizes, and degrees of accuracy to meet various requirements. For miscellaneous testing where the highest accuracy is not required, low cost is essential, and the bridge may be or must be taken to the object of the measurement, small portable bridges ("testing sets") are usually provided with self-contained battery and galvanometer. Their usual error limits are 0.1 per cent and 0.05 per cent for rheostat coils and ratio arms respectively. Larger bridges for laboratory purposes usually require an outside battery and galvanometer, although all the coils and the keys are usually mounted in one box. The coils are usually adjusted to a smaller limit of error than those in the portable bridges. Characteristic differences in laboratory bridges relate to (*a*) whether plug or dial contacts are used; (*b*) the arrangement of the ratio coils; (*c*) the number and arrangement of the coils in the rheostat arms.

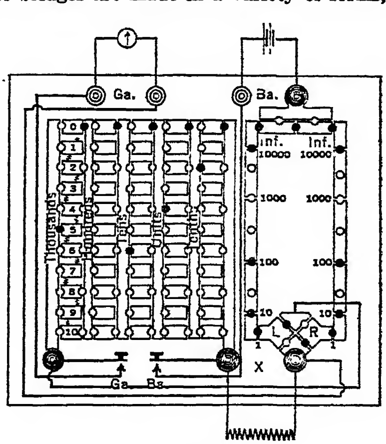

FIG. 10

The differences of arrangement of ratio coils and rheostat coils may best be brought out by brief descriptions of several classical types of bridge. Fig. 9 shows the so-called Post Office type, of English origin, with the rheostat coils arranged on the 1, 2, 3, 4 plan. The advantage of this design is the small number of coils; the disadvantage is the necessity for adding the values of the coils unplugged in the rheostat arm. Fig. 10 shows a decade bridge of the type originally devised by Professor Anthony. The resistance in the rheo-

stat arm may be read off by inspection—an advantage which is obtained at the expense of a relatively large number of coils. An important advantage of the Anthony form of bridge is that the relative values of the coils may be checked by the user. To obtain the direct-reading feature with a relatively small number of coils, special methods of connection are used in other forms of bridge by which a 9-coil "decade" is obtained with as few as 4 coils.

Special Arrangements of Ratio Coils. In the Wheatstone bridge shown diagrammatically in Fig. 11 the ratio is changed by a single sliding contact in the battery circuit where variations of its resistance have no effect on the accuracy of measurement. A comparison of the improved arrangement of ratio coils indicated in Fig. 12 with the old Post Office

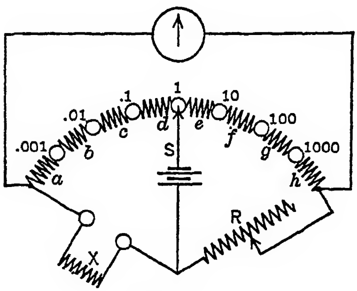

FIG. 11

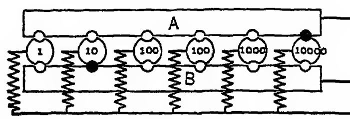

FIG. 12

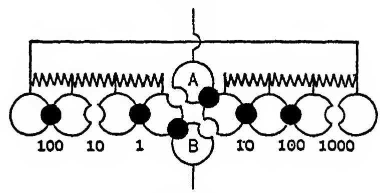

FIG. 13

arrangement of Fig. 13 shows that the former has only 2 plugs to manipulate while the latter has 6.

Accuracy of Measurements with Wheatstone Bridge. The degree of accuracy with which a resistance can be measured with a Wheatstone bridge is determined by the following conditions:

1. The limit of error to which the various coils are adjusted to their stated resistances. Limits stated by the maker usually range from 0.2 to 0.02 per cent.

2. The relative values of the coil resistances and the contact resistances at plugs, contact brushes, and binding posts. A well-fitting clean plug has a contact resistance which is definite to the order of 0.0001 ohm or better; a poorly fitting or dirty plug may fail to repeat by 0.01 ohm or more. The contact resistance between a binding post and a well-clamped wire may range from 0.0001 to 0.001 ohm. The magnitude and definiteness of the contact resistance of rotary switches depend greatly on their design. Each leaf of the laminated brush should press independently against the contact block. Rotary switches in which the thrust of the brushes is balanced about the axis of rotation are preferable, other things being equal, to those in which a considerable unbalanced force exists.

3. The relative values of the coil resistances and the insulation resistances between the contact blocks. Dust and moisture on the hard-rubber top may cause an appreciable error in high-resistance coils. Hard rubber (ebonite), which is largely used for the tops of bridges, resistance boxes, potentiometers, and volt boxes, undergoes surface deterioration when exposed to light. Such apparatus should never be exposed to direct sunlight, and should be covered when not actually in use. The deterioration goes on, though more slowly, even in diffused daylight. Dust and other impurities present in the air of cities and manufacturing centers aggravate the deterioration, which may reach the stage of a surface film of dilute acid formed from excess sulfur present in the hard rubber.

4. The effects of changes of temperature in changing the resistances of the coils and in setting up parasitic thermal emf's. Small errors from the latter source may be eliminated by taking the mean of the results of two measurements, between which the direction of flow of the battery current through the bridge is reversed.

5. Changes of resistance resulting from heating by the battery current. For any given type and size of resistor and given environment the temperature rise depends on the watts loss. Only very general figures can be given as a guide. Northrup states that the safe watt rating of the coils of a Wheatstone bridge ranges from 0.25 to 4 watts per coil, according to its construction, and that, as a rule, 1 watt should be the limit. If many coils are in use, lower values of watts per coil must be employed. It is better

to obtain sensitivity by using a sensitive galvanometer rather than by using large currents through the coils.

6. The sensitivity of the galvanometer and its relative suitability (as regards its value of external resistance for critical damping) for use with given values of resistance in the bridge arms.

Best Value of Galvanometer Resistance and Preferable Location of Galvanometer. When a choice may be made between two or more moving-coil galvanometers which differ only in the resistance of their coils, the galvanometer should be selected for which the external resistance for critical damping most nearly equals the resultant resistance R_r of the arms $A + X$ in parallel with $B + R$ (Fig. 8); namely,

$$R_r = \frac{(A + X)(B + R)}{A + B + X + R} \tag{3}$$

This is the resistance of the bridge network between the points to which the galvanometer is connected, because for the condition of balance the resistance in the battery diagonal has no effect on the value of R_r. Tradition states that the galvanometer should be selected for which the coil resistance most nearly equals the value of R as given by the above formula; that is, for example, if A, B, R, and X are each 100 ohms, that a galvanometer with a 100-ohm coil is most suitable. Such a rule could be followed when moving-magnet galvanometers were used, but to apply it to moving-coil galvanometers as now made would either result in excessive overdamping or require the insertion of additional resistance with consequent loss of sensitivity. Present-day moving-coil galvanometers which are damped only through the external circuit usually require that the external resistance for critical damping must be from, say, 3 to 15 times the coil resistance. If no galvanometer is available which complies sufficiently well with this requirement, the one which most nearly meets it may be used, resistance being placed in series with it to correct any overdamping, or in parallel with it to correct underdamping. Whenever one must choose between a moderate degree of overdamping or an equal degree of underdamping, the latter saves time and has other advantages.

In practice, the user is limited to a relatively small number of values of galvanometer resistance, and galvanometer sensitivities are usually more than ample for all ordinary purposes.

The resistance of modern batteries is so low that the old question of "best location of the battery" no longer arises; in fact, it is often advisable to insert some resistance in series with the battery to prevent damage to low-resistance bridge arms. For example, particular care in this respect is necessary when the resistance of a millivoltmeter is being measured, lest the pointer be bent and the moving coil and springs be damaged by too great a current.

Precautions in Using a Wheatstone Bridge. The following rules will conduce to accuracy of measurement and maintenance of the bridge in good condition.

1. See that all binding posts are screwed down tight and that the plugs and switch contacts are clean and properly lubricated. Plugs should be inserted and removed with a twisting motion. Only moderate force should be used in inserting them. After withdrawing a plug, retighten adjacent plugs, if necessary. The contact surfaces of the battery key and galvanometer key may need cleaning at infrequent intervals. This is conveniently done with a fine flat file.

2. For measuring all but very high resistances, use a battery of only a few volts, for example, one to three dry cells in series. The minimum voltage required to obtain the necessary sensitivity should be used. To get sufficient sensitivity when measuring high resistances (say, 100,000 ohms up to several megohms) it is generally necessary to use a greater number of cells, together with very unequal ratio arms; for example, 1 ohm and 1000 ohms. In such a case care should be taken not to use a battery voltage which will pass too great a current through any coil of the bridge, and the battery should be connected in that diagonal of the bridge which gives minimum current in the bridge coils.

3. For a preliminary balance use a 1 to 1 ratio and protect the galvanometer by shunting it or preferably by inserting a resistance of several hundred ohms (or more, according to the circumstances) in series with the battery. This resistance may later be reduced or cut out entirely.

4. Avoid touching the metal parts of keys, plugs, blocks, etc., forming part of the bridge circuit. When the circuit under measurement contains appreciable capacitance or inductance, always close the battery key first, then tap the galvanometer key momentarily to note the direction of the swing; when balance is more closely approached the galvanometer key may be held down. Always open the galvanometer key before opening the battery key when measuring coils of high time-constant, such as motor, transformer, and electromagnet windings. For these latter, allow time for the current to build up

before closing the galvanometer key. When circuits which are substantially non-inductive are under measurement, particularly in the case of low resistances, it is sometimes advantageous to close the galvanometer key first, to allow the galvanometer coil to assume a "false zero" position under the action of thermal emf, and then to close the battery key and adjust the rheostat arm to produce the condition of balance with respect to this zero position. This procedure gives the same general result as the conventional one of reversing the direction of the battery current through the bridge, but has the advantages of saving time and of eliminating the effect of all thermal emf, including that in the galvanometer.

5. If it is necessary to use connecting leads between the X posts of the bridge and the object of measurement, the outer ends of the leads should be clamped together and the lead resistance measured before making measurements on the object. This precaution is especially necessary when the leads are of flexible stranded conductor with attached terminal lugs. Defective soldered joints, or the breaking of strands of wire, may make the lead resistance variable, in which case the fact should be discovered at the beginning. If the leads are moved while the keys are depressed, small deflections of the galvanometer may occur because the leads cut the earth's magnetic field. This effect should be carefully distinguished from deflections caused by an actual variation of the lead resistance.

Care of Bridge. The hard-rubber top should be kept free from moisture and dirt, especially between the blocks; it should **never be exposed to direct sunlight,** and should be **covered** when not in use. The plugs should be free from tarnish and dirt. When necessary, they should be cleaned with whiting (never with sandpaper or emery paper) and then lightly oiled; see Resistance Boxes, Plug and Switch Contacts.

THOMSON (KELVIN) DOUBLE BRIDGE. When the resistance of a conductor is 0.1 ohm or less, an accurate measurement of its resistance cannot be made with a Wheatstone bridge, used in the ordinary way, because of the relatively large uncertainty introduced by contact resistances at the binding posts. Furthermore, in applications where the resistance of a conductor between certain points must be accurately measurable and remain definite in use, it is necessary to attach so-called potential leads to these points, thus converting the simple two-terminal conductor (or resistor) into a four-terminal resistor. Its "four-terminal resistance" is defined as the ratio of e to i, where e is the difference of potential set up between the two potential leads by a current i which enters and leaves the conductor at its ends (the "current terminals").

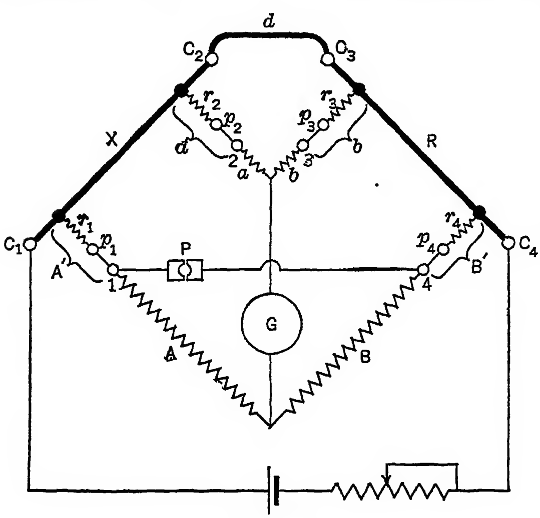

Fig. 14

A bridge network for the accurate comparison of two four-terminal resistances was devised by Wm. Thomson (Lord Kelvin) and is known as the Thomson (or Kelvin) **double bridge.** It is shown diagrammatically in Fig. 14, in which the four-terminal resistors X and R to be compared are connected in series by the link d which joins their current terminals c_2 and c_3. Current from a battery enters and leaves at the current terminals c_1 and c_4, respectively. The Kelvin bridge consists of the main ratio arms A and B and the auxiliary ratio arms a and b. In several forms of Kelvin bridge made by Leeds & Northrup Co. these ratio arms may be selected from a comparatively few values, and the four-terminal resistance of the standard R is continuously adjustable to balance the bridge by moving the potential taps. In other forms the ratio arms B and b may be selected from a few fixed values (for example, 50, 100, and 200 ohms and values made up of two or more of these), and A and a are adjustable from 0 to 1000 ohms by steps of 0.1 ohm. The arms A and a, in some constructions, are mechanically connected so that both must

have the same nominal value at all times. The binding posts 1, 2, 3, 4 in Fig. 14 are the terminals of the double bridge itself, and laboratory checks of its coils give values of resistance of A, B, a, and b up to these binding posts.

The four-terminal resistance X is actually the resistance of that part of the conductor $c_1 c_2$ lying between two points within its structure where the leads to the potential terminals $p_1 p_2$ effectively branch off. The resistances of the conductors from these branch points to p_1 and p_2 are denoted in Fig. 14 by r_1 and r_2. These resistances are usually very small, but in some special cases may be relatively large; for example, in some external shunts for d-c ammeters in which the four-terminal resistance is intentionally made too high and calibrating resistance (sometimes as much as several ohms) is added at r_1 or r_2. In any event, it is necessary to determine the effect on the measurement, not only of r_1, r_2, r_3, and r_4, but also of the resistances of the leads joining p_1 to 1, p_2 to 2, and so on. Let the resistances of r_1 plus the lead to terminal 1, r_2 plus the lead to terminal 2, and so on, be denoted by A', a', b', and B', respectively.

It may be shown that the necessary and sufficient condition for zero current through the galvanometer is

$$X = \frac{A + A'}{B + B'}\cdot R + \frac{(b + b')d}{a + a' + b + b' + d}\left(\frac{A + A'}{B + B'} - \frac{a + a'}{b + b'}\right) \tag{4}$$

This expression for X contains five unknown quantities A', B', a', b', and d, and in its present form requires a knowledge of a and b also. Most double bridges of the type under discussion are made with the intention that a/b shall equal A/B, but the lack of perfect adjustment of the coils makes these ratios slightly unequal. Certain auxiliary procedures have been devised which make it unnecessary to determine the values of A', B', a', b', d, and the exact relation between the ratios A/B and a/b. Each of these procedures makes it possible to adjust the lead resistances to give the condition that

$$\frac{A'}{B'} = \frac{A}{B} = \frac{a + a'}{b + b'} \tag{5}$$

whereupon the above expression for X assumes the convenient form

$$X = \frac{A}{B}\cdot R \tag{6}$$

One of these auxiliary procedures requires the provision of a low-resistance connection (shown in Fig. 14) which will join the terminals 1 and 4 when a plug is inserted at P. The procedure is as follows:

(a) With link d in place, joining c_2 and c_3, and plug out at P, balance the bridge by varying A and a, or B and b, so as to keep the ratios A/B and a/b nominally equal. If the extra resistances A' and B' are small compared with A and B respectively, this balance will give nearly the correct value of A/B.

(b) With link d and plug P in place, and A and B left unchanged, adjust the lead resistance forming part of A' (or of B') until balance again exists; this makes A'/B' equal to A/B, to a very close approximation.

(c) With link d out and plug out, and previous adjustments unchanged, adjust the lead resistance forming part of a' (or of b') until balance exists; this makes $(a + a')/(b + b')$ very closely equal to $(A + A')/(B + B')$ and therefore to A/B.

(d) With link replaced and plug removed, readjust the settings of A and a to get a new and more accurate balance. If the amount of readjustment required is relatively small, this balance may be regarded as final and the value of X may be found directly from the simple relation (6). If a considerable amount of readjustment is required, as may occur when a resistance of several ohms is present in one of the potential leads of X, the steps (b), (c), and (d) may be repeated until the balance obtained in any step (d) agrees closely with that obtained in the previous step (d).

Although the procedure above outlined eliminates the effect of the resistance of the link, it is important to keep this resistance as low and as definite as possible. It is customary to use a heavy copper link with its ends arranged for mercury contacts.

Other methods of making the auxiliary adjustments in measurements with the Kelvin bridge are given in papers by Wenner and Weibel (see Bibliography).

As may be seen from a consideration of step (c) in the above procedure, the coils composing the arms a and b need to be adjusted to only a very moderate degree of accuracy, and there is no object in knowing their corrections. It is also obvious that the unit in terms of which A and B are adjusted is immaterial because only the ratio of A to B is significant. Nothing would be gained, for example, by readjusting the coils of such a double bridge in terms of the "absolute" ohm to be adopted in the near future.

Besides its use for the very accurate measurements of low resistances in the laboratory,

the Kelvin bridge, in simplified form, has been adapted by several American makers for shop and field measurements of generator and transformer windings, samples of wire and cables, etc. Such instruments usually have a range of measurement of 0.0001 to about 25 ohms. The Kelvin bridge has been used by Leeds & Northrup Co. in its apparatus for continually measuring the resistance of the copper field windings of generators while in operation. The indicating (or indicating and recording) part of the apparatus is calibrated to show the mean temperature of the field winding.

HOOPES CONDUCTIVITY BRIDGE. This bridge is a modification of the Kelvin bridge, designed for the rapid determination of the relative conductivity of samples of wire. It is extensively used in wire factories. A diagram of the connections is shown in Fig. 15. The standard A–B and the unknown C–D are of the same metal; consequently if care be taken that they are at the same temperature, all corrections for temperature are avoided. The arms p, r, p_1, r_1 are in the same case and are made of material of low temperature coefficient so that their relative values will not change. They are

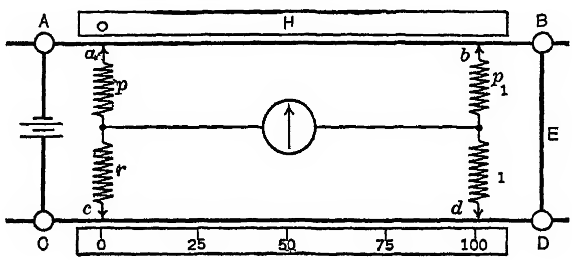

Fig. 15

adjusted so that $p = r$ and $p_1 = r_1$; consequently at balance the resistance of c–d equals the resistance of a–b.

The sample C–D is placed alongside of scale I divided into 100 parts, so that the graduations represent percentages of the total length of the scale. Accompanying the standard wire A–B is a scale H, on which are laid off a number of points corresponding to the weights of the standard length (38 in.) of a range of sizes of sample wires.

To make a conductivity reading, the weight of the standard length of the sample C–D is found to an accuracy of $^1/_{20}$ per cent. The contact b is set at the point on scale H corresponding to this weight, the contacts a and c being at the zero points of their respective scales. After the case has been closed a sufficient length of time to allow the standard and sample to assume the same temperature, the contact d is moved until the galvanometer shows no deflection; this will occur when the resistance between c and d is equal to that between a and b. The scale reading corresponding to the position of d for a balance is equal to the per cent conductivity. The bridge is designed for use with standard wire samples, each of which covers a range of sizes equal to 3 numbers of the American Wire Gage. Any number of standards can be supplied with a bridge, so that it can cover an extensive range of sizes and can also be used for wires of different materials. In order to keep the standard wire and the test wire at the same temperature the bridge is mounted in a metal-lined case and the scale is read through a glass window in the case, the window being closed by a metal screen when readings are not being taken.

BRIDGES FOR MEASURING THE RESISTIVITY OF ELECTROLYTES. The resistance of an electrolyte contained in a suitable cell can be measured by using a Wheatstone bridge with an a-c detector and an a-c source substituted for the battery. Alternating current must be used on account of the polarizing action of a direct current. Suitable **a-c sources** are: ordinary 25-cycle or 60-cycle circuits; a small 1000-cycle generator; a "microphone hummer" which is a combination of electrically operated 1000-cycle fork, a microphone, and a transformer, the secondary of which supplies 1000-cycle current; a buzzer operated by dry cells, with a transformer having its primary winding in series with the buzzer and its secondary winding connected to the bridge.

A telephone receiver is a suitable detector when a 1000-cycle source is used, but is not suitable for low frequencies such as 60 cycles. For the latter, an a-c galvanometer of the separately excited moving-coil type, or of the vibration type, is necessary. With the moving-coil galvanometer separately excited by a current in phase with the bridge currents it is sufficient if the three arms of the bridge (other than the one formed by the cell containing the electrolyte) are non-reactive. With the vibration galvanometer or

the telephone receiver there must be a condition not only of resistance balance but also of phase balance, and the coils must have good a-c and good d-c characteristics. One way to obtain the phase balance is to use an adjustable air condenser connected across one of the arms of the bridge.

Cells for containing the electrolyte are usually made of glass and have fixed electrodes of platinum or gold. Each cell is calibrated by one or more measurements with the cell filled with liquid of known resistivity, in order that the measured *resistance* of any sample of liquid may be reduced to its *resistivity*. A cell of the immersion type for approximate measurements may be extemporized from a glass tube of known internal diameter, in the ends of which circular electrodes are secured at a measured distance apart. There should be several small holes in the wall of the tube. In use, the cell is immersed in a vessel containing the electrolyte to be tested. The resistivity is the product of the cross-sectional area of the tube and the observed resistance, divided by the distance between the electrodes.

A-C BRIDGES. Bridges for the measurement of inductance, capacitance, and other quantities of importance in a-c circuits have been developed in a great variety of forms and for use over widely varying ranges of frequency. With few exceptions, they have hitherto usually been assembled in the laboratory from component pieces of apparatus. Recently, however, a-c bridges as self-contained units have been developed and are being manufactured. Space limitations prevent an extended treatment of this subject, for which the reader is referred to the book by Hague (see Bibliography). See also Schering Bridge, in the section on Testing of Insulating Materials.

8. POTENTIOMETERS

DEFINITIONS. A potentiometer is an instrument for measuring an unknown emf or potential difference by balancing it, wholly or in part, by a known potential difference produced by the flow of known currents in a network of circuits of known electrical constants. In d-c potentiometers the only network constants involved are the resistances, but in a-c potentiometers the capacitances and the self and mutual inductances of the network also enter into the result, as well as the frequency.

In potentiometers of the **null type** the unknown emf or potential difference is completely balanced, and the galvanometer (or other detector) merely indicates the absence of a current. In the **deflection potentiometer** a part of the unknown voltage produces a current through the galvanometer, which is calibrated to read directly the corresponding part of the measured value.

USES OF THE D-C POTENTIOMETER. For the checking of d-c ammeters, voltmeters, and wattmeters the d-c potentiometer is recognized as the most accurate instrument available. In most forms it has the unique advantage that only the *relative* values of its coils are of importance, and these values, in other than complicated designs, can often be adequately checked by the user even though the absolute values of his standards are not known. With suitable resistance standards of appropriate current ratings, the potentiometer may be used to measure direct currents over a wide range; and with suitable "volt boxes," it will measure voltages up to several thousand volts.

Auxiliary devices for the potentiometer proper for d-c measurements are a cell or battery to supply the auxiliary current, a rheostat to adjust this current, a standard cell, and a galvanometer. In some forms of potentiometer, some or all of these auxiliary devices are built into the instrument.

PRINCIPLE OF THE D-C NULL-TYPE POTENTIOMETER. The d-c potentiometer in its simplest form (Fig. 16) consists of a uniform wire stretched over a scale divided into a number of equal divisions; for example, 1500. A storage cell B, having an emf of about 2 volts, and a rheostat R are connected in series with the wire, and two contact points are provided, A being fixed at the zero point and S being movable. G is a galvanometer and K is a key for the galvanometer circuit. Between the terminals at P there may be connected at will a standard cell or any unknown voltage. At P is first connected a standard cell, for example, an unsaturated cadmium cell having an emf of 1.0190 volts. The terminal of B and that of the standard cell which are connected to the point A must have like polarities. The contact S is set at 1019 divisions on the

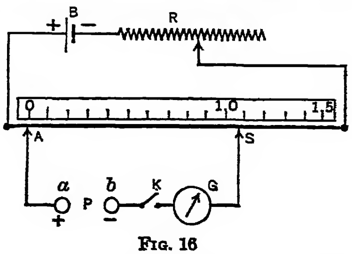

FIG. 16

scale, and the rheostat R is adjusted by trial until the closing of the key K produces no deflection of the galvanometer.

To measure any other potential difference the standard cell is disconnected from the terminals a and b and the unknown potential difference, for example, that of an ammeter shunt, is connected to a and b. The contact S is then moved until a position is found such that the closing of K produces no deflection. The corresponding position of S on the wire, as read from the scale, gives the value of the unknown potential difference.

Although the simple slide-wire potentiometer is sufficiently accurate for some technical purposes, its range and accuracy are inadequate for precision laboratory measurements, such as the checking of high-grade indicating instruments. Many forms of precision potentiometer have been devised, of which a few typical ones only can be described.

POTENTIOMETERS WITH ONE DIAL AND A SLIDE WIRE. An obvious modification of the above simple potentiometer is the insertion, in series with the slide wire, of a set of coils, each having a resistance equal to that of the slide wire between the zero and the point 1.0. Fig. 17 shows such a potentiometer (Leeds and Northrup type K). The slide wire DB is 11 turns of manganin wound in an external screw thread cut on a Bakelite cylinder. It is shunted to a resistance of 5.5 ohms and is in series with fifteen

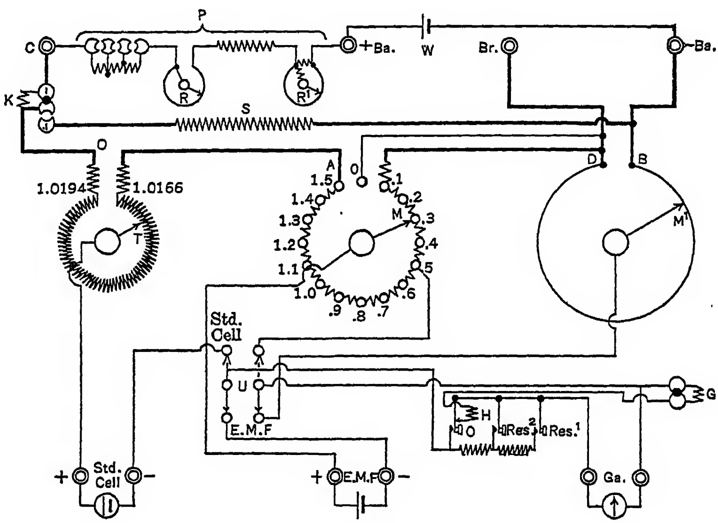

FIG. 17

5-ohm coils connected to studs, over which runs the brush M. The rheostats P are for adjustment of the auxiliary current. The other slide wire, over which runs the slider T, adapts the potentiometer to be direct reading with any standard cell having an emf within the slide-wire range. Although this range permits the use of standard cells of emf as low as 1.0166 volts, cells having an emf below 1.0180 should not be used for precise measurements because unsaturated cadmium cells of lower value are apt to be unreliable under ordinary conditions of varying room temperature.

A double-throw switch U inserts the galvanometer, with its keys and protective resistors, either in the standard-cell circuit or in the unknown-emf circuit. Keys Res. 1, Res. 2, and 0 are closed in the order stated to protect the galvanometer from violent deflections and the standard cell from currents which might (at least temporarily) alter its emf.

The function of coil K, the plug switch near it, and the coil S is to permit, after adjusting the battery current properly, with the plug set at 1, the shunting of nine-tenths of the current through coil S while keeping the total battery current unchanged. The potentiometer current is thus reduced to one-tenth of its normal value, and the normal range of 0 to 1.61 volts is thereby reduced to 0 to 0.161 volt.

The procedure of operation just outlined is typical for d-c potentiometers. For any particular potentiometer, the maker's instructions should be consulted for details.

The **Type K-2** potentiometer (Leeds & Northrup Co.) retains the slide wire and

set of coils of the Type K potentiometer, but includes a new low range of 0 to 0.016 volt. The constancy of the auxiliary current can be checked, by reference to a standard cell, regardless of which range factor (1, 0.1, or 0.01) is in use. This is accomplished as shown in Fig. 18. The coils of the main dial and the slide wire are shunted by four coils in series having resistances of 424.5, 300, 72.45, and 8.05 ohms, respectively. Taps from

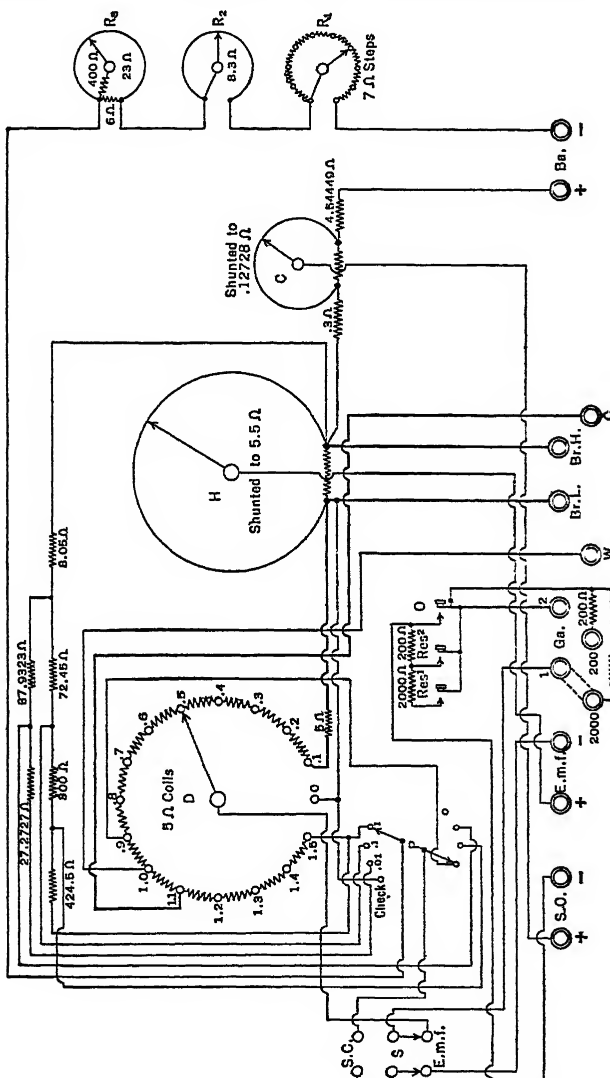

FIG. 18

junction points in this shunt circuit run to the points marked 1, 0.1, 0.01 on the factor switch P, the tap to the point 0.01 containing two coils in series having resistances of 27.2727 and 37.9323 ohms, respectively. These resistances are such that if the total current from the auxiliary battery Ba be adjusted in the usual manner to produce a current of 0.02 amp through the main dial and the slide wire with the factor switch set at 1,

the shifting of the factor switch to the position marked 0.1 will redistribute the auxiliary current, without altering its total value, so that only 0.002 amp flows through the main dial and the slide wire. With the factor switch at 0.01, the current is again redistributed, without change of total value, so that the current through the main dial and the slide wire is reduced to 0.0002 amp. For each distribution of current the lower part of the factor switch P connects the − pole of the standard cell to a junction point on the network such that, if the condition of balance (zero current in the galvanometer) existed with the factor switch set at 1, it will exist for each of the other two positions of this switch.

The Type K-2 potentiometer has three extra taps from the main-dial coils to external binding posts. Two of these taps include exactly 1 volt and are used with a volt box in wattmeter testing where it is required to hold the test voltage constant at 100 volts. This feature makes it possible to check the voltage without regard to the positions of the dial switch D and the slider H, and in effect makes the potentiometer read directly in watts. One of the preceding taps and a third tap serve in the checking of the 11 turns of the slide wire H against the first 11 coils of the main dial.

The Type K-2 potentiometer differs from the Type K in the following structural details: All contacts are inclosed; the battery rheostats are all dial-controlled; the change from emf to standard-cell check, and the change of range, are effected by dial switches instead of the rocker switch and plug switch, respectively, of the Type K.

WHITE COMBINATION POTENTIOMETER. This is a low-resistance instrument designed to minimize parasitic thermal emf, and is intended particularly for precise measurements of temperature with thermocouples. A simplified diagram of the White "single potentiometer" is shown in Fig. 19. In the White "double potentiometer," an additional set of dials is provided, to permit measurements with two separate thermocouples at widely different temperatures without extensive and repeated changes of the dial settings.

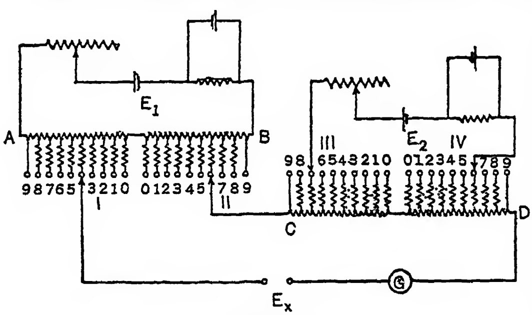

FIG. 19

WENNER POTENTIOMETER. This is a recent low-resistance five-dial potentiometer, in which the galvanometer circuit resistance is maintained substantially constant at either 40 or 174 ohms. The instrument has two ranges of 0 to 1.9111 and 0 to 0.19111 volt. It is described by Behr in *Rev. Sci. Insts.*, 1932, vol. 3, p. 109.

WOLFF FIVE-DIAL POTENTIOMETER, FEUSSNER TYPE. In this potentiometer, shown diagrammatically in Fig. 20, the auxiliary current entering at $B+$ flows through the nine 100-ohm coils of the upper right-hand dial, then through the coils of the lower halves of the 0.1-, 1-, and 10-ohm double dials, through the 1000-ohm coils, then through the upper halves of the 10-, 1-, and 0.1-ohm double dials. These three

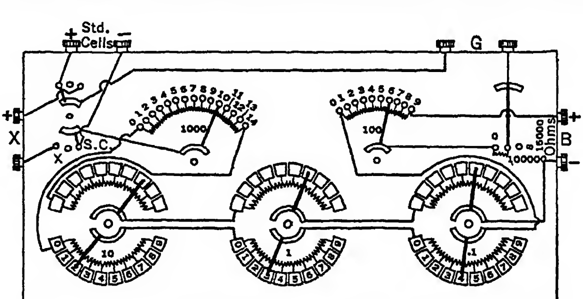

FIG. 20

double dials vary the resistance between the zero studs of the two upper dials from 0 to 99.9 ohms by steps of 0.1 ohm while keeping the total resistance between the terminals B constant at 14,999.9 ohms. With the auxiliary current commonly used (0.0001 amp) the range of measurement is 0 to 1.5 volts, approximately. An external rheostat is required for adjusting the current, which may be supplied by a single storage cell or by two dry cells in series. In either case it is not necessary to open the battery circuit when the potentiometer is out of use. In one form of Wolff potentiometer, in order to check the value of the auxiliary current it is necessary to set the dials to the value of the emf of the standard cell and to set the double-pole double-throw switch in the upper left-hand corner to S.C. In a later form a separate standard-cell dial is provided, having 11 steps for 1.0180 to 1.0190 volts. This feature makes it possible to check the auxiliary current quickly without the necessity of setting the regular five dials to the value of the standard cell.

EPPLEY FIVE-DIAL POTENTIOMETER, FEUSSNER TYPE. This potentiometer is similar to the Wolff potentiometer in plan of circuits and values of coils, but has a number of refinements, including: the elimination of six of the twelve contact resistances in the measuring circuit; an additional standard-cell dial by which the standard-cell setting can be made to one more decimal place (namely, to 0.00001 volt); copper binding posts to minimize parasitic thermal emf; built-in rheostats for the adjustment of the auxiliary current; and provision for oil immersion and control of oil temperature. The additional standard-cell dial is obtained by bringing out taps from one of the 1000-ohm coils.

INCREASING THE RANGE OF VOLTAGE MEASUREMENT. To measure voltages greater than the maximum directly measurable with the potentiometer, an accessory variously known as a "multiplier," "potential divider," or "volt box" is used. (The first two names imply respectively that the accessory *multiplies* the range of the potentiometer or *divides* the line voltage to get a fraction which can be measured.) It consists essentially of a high resistance to be connected to the points between which the voltage is to be measured, with the potentiometer connected across a fractional part of the resistance. The reading of the potentiometer, multiplied by the reciprocal of this fraction, gives the value of the voltage to be measured. Volt boxes are usually multirange. Two general types of volt-box circuit are shown in Fig. 21. In (*a*) the total resistance is varied to change the range, and in (*b*) the resistance across which the potentiometer is connected is changed. In (*a*) there is the danger of burning out the coils by applying too high a voltage to a part of the total resistance meant for measurements of relatively low voltage. In (*b*) this danger does not exist, but when the lower ranges are in use the volt box may introduce an excessive amount of resistance into the measurement circuit, thereby reducing the sensitivity. There is the further disadvantage in arrangement (*b*) that if a high voltage is applied to the line posts while the switch is set for a low ratio an abnormally high voltage will be impressed on the potentiometer and the galvanometer is very easily damaged. This trouble is possible even with arrangement (*a*), but experience shows that it is very rare. Experience shows also that separate "line" binding posts for the various ranges are safer than a rotary switch.

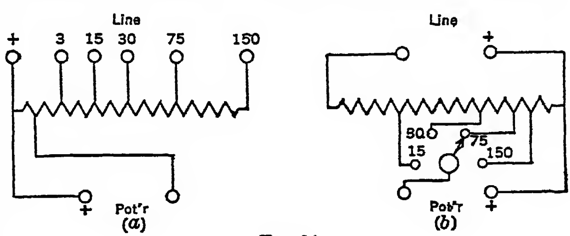

FIG. 21

The combination of a potentiometer with a volt box is not a null instrument, and for accurate work a correction must be made for the resistance of the leads connecting the line terminals of the volt box to the points between which the voltage is to be measured. For a given resistance in the leads, this correction is smaller as the resistance of the volt box is greater. Furthermore, a high value of "ohms per volt" is desirable because it reduces the self-heating of the volt box. The considerations which act to set an upper limit to the ohms-per-volt are the greater cost and lower stability of high-resistance coils, the greater effect of leakage over the insulating surfaces, and the reduction in sensitivity caused by the large resistance which the volt box contributes to the measurement circuit.

MEASUREMENT OF DIRECT CURRENTS. The current to be measured is passed through a four-terminal resistance standard having its potential terminals joined to the emf terminals of the potentiometer. The measured potential difference, divided by

the four-terminal resistance of the standard, gives the value of the current in amperes. For convenience, the values of the four-terminal resistance are often decimal submultiples of an ohm (0.1, 0.01, etc.), in which case the numerical result of the measurement in volts, multiplied by 10, 100, etc., gives the value of the current in amperes.

DEFLECTION POTENTIOMETERS. In the potentiometers described above, the galvanometer is commonly used merely as a detector, although it is feasible to interpolate between adjacent steps on the lowest dial by noting the corresponding galvanometer deflections. In the deflection potentiometer the greater part of the measured result is read from the dial and the galvanometer is calibrated to indicate directly the last two figures of the result. The only difference between the circuits of an ordinary potentiometer and those of a deflection potentiometer is that the latter has supplementary coils which maintain a constant resistance in the galvanometer circuit for all positions of the switch of the potentiometer dial and those of the battery rheostats, as well as for all values of resistance in the volt box and in the shunts used for current measurements.

The accuracy and precision of the deflection potentiometer are intermediate between those of an ordinary ammeter or voltmeter and those of a high-precision null-type potentiometer. It is used for the checking of ammeters, voltmeters, and wattmeters, and for current and voltage measurements in photometry.

PRECAUTIONS IN THE USE OF D-C POTENTIOMETERS. The emf of a storage cell is unsteady immediately after charging and decreases rapidly for a time. The cell is unfit for use with a potentiometer during this period. The emf of storage cells and of dry cells changes with temperature, and for the most accurate results the cells should be protected from abrupt changes of temperature. The temperature coefficient of emf of dry cells is about twice that of storage cells, the values being about 0.02 per cent and 0.01 per cent per degree centigrade, respectively.

Potentiometers should not be unnecessarily exposed to dust, moisture, or chemical fumes, and should be *kept covered* when not in use. When the top is of hard rubber it should *not be exposed to direct sunlight*, which will cause deterioration of its surface and greatly impair its surface resistivity.

The galvanometer and all the other accessories of the potentiometer should be carefully insulated to avoid leakage currents from other d-c circuits. It is often necessary or desirable to apply the Price "guard-wire" method of protection, in which the potentiometer and each of its auxiliaries, including the galvanometer, are supported by, but insulated from, metal plates which in turn are preferably insulated from the table or other support. These guard plates are connected together and to that pole of the circuit, supplying the current or the voltage under measurement, which is more nearly at earth potential. The line terminal of the volt box (the + terminal in Fig. 21) which in use is connected directly to the potentiometer is to be connected to this pole of the supply circuit, and the shunt used for current measurement should be connected in this side of the line. If the potential of this side of the line unavoidably differs appreciably from earth potential, it is advisable to apply the guard plates to the observer's chair also.

The wires connecting the guard plates together should be protected against breakage. W. P. White has proposed a series connection of the guard plates, so that a single test of the resulting loop checks all the wires for continuity.

When the atmosphere is very dry, as in heated buildings during the winter, disturbances of the galvanometer may result from static charges on the clothing of the observer. This difficulty has been found very troublesome with fur-trimmed garments.

The following practice should be observed in order to avoid accidental short-circuiting of the standard cell. In connecting a standard cell to a potentiometer, first attach *both* wires to the potentiometer, then connect the outer ends of the wires to the cell. In disconnecting the cell, first remove the wires from it. It is well to disconnect one wire from the cell at the end of the day even though the apparatus will be used the next morning. The cell should never be removed with the two wires still attached to it.

A-C POTENTIOMETERS. Referring to the simple potentiometer of Fig. 16, let a milliammeter be inserted in circuit to measure the current in the slide wire. It should be of such type as to give equally accurate readings on direct current and on alternating current of the frequency to be used. After the direct current through the slide wire has been adjusted to the standard value, the reading of the milliammeter should be noted; if this reading depends somewhat on the direction of current flow through the milliammeter, the mean of two readings, between which the direction of flow through the milliammeter is reversed, should be taken. The battery B is then replaced by an a-c source and the rheostat R is adjusted until the reading of the milliammeter is the same as on direct current. The unknown alternating voltage is then connected at P and the d-c galvanometer replaced by a suitable a-c galvanometer or other detector. The unknown voltage must have the same frequency as the current through the potentiometer.

This condition is ordinarily fulfilled by taking both from the same source, or from generators which are mechanically coupled. To obtain a balance, the potential difference taken from the slide wire not only must have the same magnitude as the unknown potential difference but also must be in phase with it. Means must therefore be provided for shifting the phase of the current through the slide wire. In the **Drysdale potentiometer** this is done by means of a phase-shifting transformer. This potentiometer is of the polar-coordinate type; that is, it gives the magnitude of the unknown emf and its phase with respect to a reference vector.

The first a-c potentiometer of the cartesian-coordinate type was devised by **Larsen,** and its principle of operation is shown in Fig. 22. An alternating current i of a standard value flows through the slide wire AB and the primary winding of the adjustable mutual inductor M. The potential difference which balances the unknown potential difference E_x is made up of a component taken from the slide wire, in phase with i, and a quadrature component $2\pi fiM$ induced in the secondary winding of M. Since the potentiometer must usually be available for a range of frequencies, the scale of M must be marked in terms of mutual inductance, and its readings must be multiplied by $2\pi fi$ to reduce them to volts.

Erlang and Pedersen proposed other forms of a-c potentiometer, especially suitable for investigations of telephone apparatus, but not so well adapted for power frequencies.

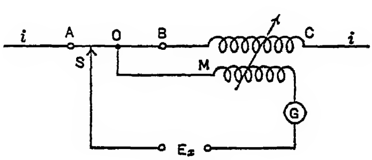

FIG. 22

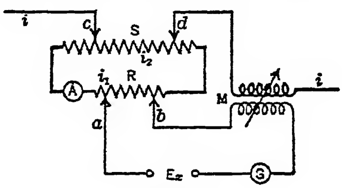

FIG. 23

See Bibliography. The Gall a-c potentiometer, made by H. Tinsley & Co., is an assembly of two potentiometers to form a single piece of apparatus. In use, the two potentiometers are traversed by currents mutually in quadrature. The **Geyger a-c potentiometer,** made by Hartmann & Braun, consists of two center-zero slide wires, one fed from the secondary of an insulating transformer through a non-inductive resistance, the other from the secondary of an air-core transformer having its primary in series with the first slide wire. The **Campbell-Larsen a-c potentiometer,** made by Cambridge Instrument Co., is shown diagrammatically in Fig. 23. The operation is like that of the Larsen potentiometer, but the troublesome multiplication by $2\pi fi$ is avoided. To balance the unknown voltage E_x, two components are required; one is taken from the non-inductive resistance R by adjusting the sliders a and b, and the other by adjusting the value of the mutual inductance M. The current i through the primary of M is composed of the current i_1 through R plus the current i_2 through S. The current i_1 is set at a standard value by means of the device A, which consists of a heating device, a thermocouple, a resistor, and a galvanometer to indicate when the effective value of i_1 is equal to an auxiliary direct durrent of standard value. By adjusting the position of the contacts c and d the total current i corresponding to the standard value of i_1 may be made such that the scale of M indicates directly the emf induced in the secondary of M, in millivolts, at the given frequency. The range of frequency for which this can be done is 25 to 2000 cycles per second. The scales for the sliders a and b are also graduated in millivolts.

Uses of the A-C Potentiometer. Although the a-c potentiometer was originally advocated as a standard instrument for checking ammeters, voltmeters, and wattmeters, the inherent limitations on its accuracy and the other improved apparatus now available for a-c instrument checking make it inadvisable to purchase an a-c potentiometer for this purpose. The accuracy of measurement of the effective value of a given alternating emf or current with the average a-c potentiometer may be assumed to be from 0.5 to 1 per cent for the usual power and lighting frequencies, when the wave form of the quantity to be measured and that of the current through the potentiometer are closely alike and sinusoidal. The real usefulness of the a-c potentiometer lies in fields of engineering research, testing, and investigation where an accuracy of about 1 per cent is adequate and where the measurements either could not be made at all by other means or would be very difficult to carry out. The a-c potentiometer has been used with good results for studying the actions which take place in induction meters and other a-c measuring

apparatus; in magnetic analysis; for measuring the magnetic properties of laminated steel, the ratio and phase angle of current transformers, and the amplification factors of amplifiers. The success of work of this kind depends very much on the manner of setting up and manipulating the potentiometer and the related apparatus, and those who wish to apply the a-c potentiometer method to their problems may consult with advantage papers by Spooner, Geyger, and von Krukowski (see Bibliography).

9. LABORATORY MEASUREMENTS OF D-C. POWER AND ENERGY

For the precise measurement of d-c power in the laboratory, where the current and voltage are supplied by batteries and can be kept very constant, the accepted technique is to measure the current and the voltage by means of a potentiometer, volt box, resistance standard, and standard cell, as indicated in the preceding section on Potentiometers. Measurements of d-c power with such equipment are made in checking the correctness of wattmeters. The same procedure, with the addition of the measurement of time intervals, is the accepted method for the checking of portable standard d-c energy meters (watthour meters).

10. LABORATORY MEASUREMENTS OF ALTERNATING CURRENT, VOLTAGE, AND POWER

GENERAL. The measurement of the instantaneous values of alternating current, voltage, and power requires the use of instruments such as are described in the section on Oscillographs. The majority of a-c measurements, however, refer to conventionally defined and universally recognized effective (or root-mean-square) values. An alternating current of 1 amp, effective value, flowing through a circuit having a resistance of 1 ohm, will liberate heat at the same rate as if 1 amp of direct current were flowing through this circuit. It follows that electrothermic instruments are suitable in principle for the measurement of effective values of alternating currents. Although such instruments are necessary for measurements at high frequencies, they have limitations which have caused two other types to be preferred for precision laboratory measurements at the frequencies used for power and lighting. These are the electrostatic and the electrodynamic types.

METHODS USED BY NATIONAL LABORATORIES. Methods employing electrostatic instruments are preferred for precision a-c measurements by the British National Physical Laboratory. The National Bureau of Standards at Washington prefers instruments of the electrodynamic type. These instruments are of the reflecting type, with the moving-coil system carried by upper and lower suspension strips. The deflection is observed by means of a lamp-and-scale arrangement. The moving-coil system has two coils of unlike instantaneous polarity in order to make the instrument astatic as to uniform stray fields. The arrangement and connection of the windings in order to serve for current, voltage, and power measurements are the same (in the older instruments long used at the Bureau) as the corresponding features in the portable and laboratory-standard electrodynamic instruments so widely used, and the reader is referred to the subsequent treatment of such instruments. In Bureau practice, these instruments are checked on direct current, using a potentiometer, standard cells, and resistance standards, immediately before and after a pair of a-c observations; that is, they serve to carry over or transfer the a-c measurements to the units embodied in these basic d-c standards. They are accordingly spoken of as "transfer instruments." Although this method avoids some of the sources of error which attend the use of standard instruments which are checked at only occasional intervals (of weeks or months), some sources of error remain. These have to do chiefly with the limited accuracy of reading the deflection and the not wholly satisfactory elastic performance of the bronze suspension strips which carry the moving-coil system.

In recent years newer transfer instruments have been devised at the Bureau to overcome these limitations. One is the Harris suppressed-zero electrodynamic voltmeter, the other the Silsbee composite-coil electrodynamic ammeter. In the former the entire deflecting torque is balanced by the torque of the suspensions, as in the older transfer instruments, but the coil system is restrained by two stops so that it cannot return to zero when the current ceases to flow. The continual, nearly constant stress in the suspensions eventually results in a steady state such that "zero drift" is eliminated to a very high degree. In the Silsbee composite-coil ammeter each of the fixed coils and each of the moving coils is wound with a pair of wires, and in operation the deflecting torque resulting from the alternating current is nearly balanced by the counter torque set up

by a precisely adjusted direct current in the other circuit through the coil system. Small variations in the magnitude of the alternating current are measured by observing the deflection of the coil system to the right or to the left of its central zero position.

TRANSFER INSTRUMENTS FOR GENERAL USE. Reflecting electrodynamometers are used for the measurement of very small amounts of power at low power factor, as in the testing of samples of cable for dielectric loss. For many purposes, however, in commercial laboratories electrodynamic voltmeters, wattmeters, and ammeters of the pivoted type, with pointer and scale, are of satisfactory accuracy and are much more convenient. The inductance of their circuits can be kept small by suitable design, and corrections are usually small and not difficult to apply. However, for the measurement of very small amounts of power at high voltage, or for measurements at frequencies much above the usual power and lighting frequencies, the effects of the unavoidable inductances of the electrodynamic instrument become sufficiently pronounced to warrant the use of an electrometer in spite of its more delicate construction and much longer period.

11. ELECTRICAL INDICATING INSTRUMENTS

GENERAL. An **electrical indicating instrument** is an instrument in which the present value of the quantity under observation is indicated by the position of a pointer relative to a scale. The term "instrument" may include the instrument proper, as defined below, or it may include the instrument proper together with any necessary auxiliary devices, such as shunts, shunt leads, resistors, reactors, capacitors, or instrument transformers. The **instrument proper** consists of the actuating mechanism together with those auxiliary devices (scale, resistors, shunts, etc.) which are built into the instrument case or otherwise made an integral part of its structure.

The large output of electrical instruments and the wide diversity of their applications have made an American code of standard definitions and terminology necessary in order to facilitate a clear understanding between the specifying engineer, the purchasing agent, and the manufacturer. The beginning of such a code has been provided by the A.I.E.E. in its Standards No. 33 for Electrical Indicating Instruments.

DISTINCTION BETWEEN ERROR AND CORRECTION; ACCURACY OF AN INSTRUMENT. The error of indication of an instrument is found by subtracting from the value which it indicates the true value of the quantity measured by it, as determined by reference to some standard of a higher order than the instrument itself. It is the quantity which must be **algebraically subtracted** from the indication to obtain the true value of the quantity. A positive error thus denotes that the instrument "reads high," that is, that its indication is greater than the true value. The **correction to the indication** is found by subtracting the indicated value from the true value, that is, the correction has the same numerical value as the error of indication, but the opposite sign. **The correction, algebraically added** to the indication, gives the true value.

The **accuracy of an instrument** may be expressed in various ways, some of which are ambiguous and likely to cause disagreement between maker and purchaser. It is generally defined as the ratio of the error of indication to some like quantity taken as a basis. If the indication were taken as the basis it would be necessary to have a sliding scale of accuracy with the permissible percentage error increasing in some manner as the deflection decreased. The majority of American manufacturers consequently favor the simple definition of accuracy as the percentage ratio of the limit of error at any point on the scale to the full-scale value. In instruments having uniform scales this is equivalent to saying that no division mark is out of its proper position by more than a specified distance. This definition of accuracy applies to the usual case in which the zero point is at the lower end of the scale. For instruments in which the zero point is in an intermediate position on the scale, the sum of the full-scale readings to the right and to the left of the zero point should be used as the basis for reckoning the accuracy.

The accuracy of an electrical instrument depends on the operating principle; the quality of the design, materials, and workmanship; and the conditions of use. In general, the accuracies stated by American instrument makers are about as follows: switchboard instruments, 4 in. diameter and larger, 1 per cent; 3 in. diameter and smaller, 2 per cent; laboratory-standard instruments, 0.1 per cent; portable instruments, highest-grade, 0.2 to 0.25 per cent, intermediate-grade, 0.5 to 0.75 per cent; miniature instruments, 2 per cent. Exceptions: high-grade portable polyphase wattmeters, 0.5 per cent; rectifier instruments, for which relatively large errors must be tolerated; frequency meters, power-factor meters, phase-angle meters, and capacitance meters, the accuracy of which must be stated in special ways for which the makers' catalogs should be consulted.

Although a high degree of accuracy is important in much laboratory work and in such

Electrothermic instruments depend for their operation on the heating effect of a current. Two markedly distinct types are (1) the **expansion type,** commonly known as the hot-wire type, and (2) the **thermocouple type.** In the hot-wire instrument the indication is effected by mechanically multiplying the expansion of a wire or strip which is heated by the current. Hot-wire instruments have been virtually superseded by instruments of the thermocouple type, in which one or more thermojunctions are heated (directly or indirectly) by the current and supply a direct current which actuates a suitable d-c instrument mechanism. Both the hot-wire and the thermocouple types may be made as ammeters, voltmeters, and wattmeters. Among the **advantages of the thermocouple instrument** over the hot-wire instrument are: much lower power loss, greater sensitivity, and ability to measure currents down to very much smaller values. Like the hot-wire instruments, the thermocouple instruments are **easily damaged by overload.** For example, Hartmann and Braun state that the heating element of their vacuum thermocouple will burn out when the current reaches 1.6 times its rated value; for a 1-amp and a 10-amp heating element the fusing currents are given as twice rated current and three times rated current, respectively. The "thermal inertia" which brings most instruments through momentary inadvertent overloads without thermal damage is so small in the thermocouple instrument that even careful users must count on burning out a heating element occasionally.

Ammeters of the thermocouple type are suitable for use on alternating current of frequencies ranging from the lowest up to those employed in radio circuits. They are not ordinarily used at power frequencies, but have advantages in special cases where minimum resistance and negligible inductance are necessary. They are indispensable for measurements at audio and higher frequencies. Self-contained thermocouple ammeters are made in ranges from 2 ma up to 50 amp. They are supplied with external heating elements up to 1000 amp. Multiple-range milliammeters, because of the necessity for passing part of the current through a shunt around the heating element, are limited to a maximum frequency of 3000 to 5000 cycles. This limitation does not apply to multiple-range instruments in which a separate heating element is used for each range.

Voltmeters of the thermocouple type may be used with frequencies up to 3000 to 5000 cycles.

Electrostatic instruments depend for their operation on the forces of attraction or repulsion between electrically charged fixed metal parts and moving metal parts. The relatively weak forces developed in this way tend toward an undesirably long period and other operating drawbacks, and limit the application of electrostatic instruments to particular purposes for which their special advantages make them preferable or even indispensable. They are useful when voltage measurements are to be made without drawing any appreciable current from the source, or when the cost of series resistors or of voltage transformers for high voltages would be prohibitive. They are practically the only means available for measuring direct voltages of 100 kv or more as used in cable testing. They are designed either for direct connection to the points between which the voltage is to be measured, or through an electrostatic voltage divider analogous to the "volt box" used with a potentiometer. The use of such voltage dividers is feasible for a-c voltage measurements only.

Electronic (thermionic) instruments utilize for their operation the properties of the electronic tube. These instruments are in the early stages of development, and their construction and application have not yet been standardized. Results may be obtained with them that are not possible with instruments of any other type. For example, the thermionic voltmeter described by S. C. Hoare (see Bibliography), having a 5-volt range, can be made to function as if its internal resistance were 50,000 ohms when a 6-volt auxiliary battery is used. With a 24-volt auxiliary battery the voltmeter behaves as if its resistance were infinite. The same type of instrument can be made as a microammeter giving full-scale deflection for 0.1 ma and having an equivalent resistance of 3.3 megohms. These instruments are subject to errors when the wave form is other than that used in their calibration, and they have some other special limitations concerning which Mr. Hoare's article and others (see Bibliography) should be consulted.

RECTIFIER INSTRUMENTS. A rectifier instrument is the combination of an instrument responding only to direct current and a device for rectifying the alternating current to be measured. Instruments of this type are usually of the permanent-magnet moving-coil type in combination with **copper-oxide rectifiers** in the Wheatstone-bridge full-wave arrangement. They have been developed to meet the need for low-range a-c ammeters and voltmeters of very small power consumption. They are used for those a-c measurements for which the relatively large power consumption of electrodynamic, thermocouple, and moving-iron instruments makes them ill-adapted or even inappli-

cable, also for a-c measurements where only moderate accuracy (say 5 per cent) is sufficient and ruggedness and ability to sustain overloads are important. The deflection of a rectifier instrument is proportional to the **average value** of the rectified wave, but since the user is generally concerned with the effective value, it is customary to mark the scales in terms of the effective (rms) values for an assumed (usually sine) wave form. It is possible to make a-c voltmeters of the rectifier type with as high as 2000 to 4000 ohms per volt, and ammeters giving full-scale deflection for as little as 500 ma. Rectifier instruments not only are subject to relatively large **wave-form errors** but also are noticeably affected by changes of room temperature. For details as to the magnitude of these effects, methods of compensation for temperature, etc., reference should be made to the maker's instructions and to papers by Sahagen and others (see Bibliography). **Rectifier ammeters** are available in ranges of from 100 to 500 ma. **Rectifier voltmeters** are made in ranges of from 2 to 150 volts. Rectifier instruments are of relatively recent origin and have not reached the stage of standardization which characterizes most other types. The makers should be consulted for the latest information about rectifier instruments for specific requirements, particularly since the accuracy of these instruments is so dependent on temperature and wave form.

WATTMETERS. General. A wattmeter measures the average value of the product ei of the instantaneous voltage by the instantaneous current; that is, the average power. Types of instrument which may be adapted for use as wattmeters include the electrodynamic, induction, electrostatic, hot-wire, and thermocouple. Even the moving-iron instrument may be so used, but though patents for such wattmeters have been issued, no practical use appears to have been made of them. For the use of electrostatic wattmeters, see **Electrometers.** For most purposes the electrodynamic wattmeter is preferred, and the discussion in this section is limited to this type.

The **electrodynamic wattmeter** consists essentially of two coils, one of relatively coarse wire carrying the load current, and the other, of fine wire, in series with a noninductive resistor, connected in parallel with the load. The current in the fine-wire coil being very nearly in phase with the voltage e across the load, the instantaneous torque will be closely proportional to the instantaneous power. Because the natural period of vibration of the moving coil is so much greater than the period of an alternating current, the coil does not follow the rapid cyclic changes of the instantaneous power but assumes a deflected position which indicates the average power. The torque produced by the currents in the coils is opposed and balanced by a counter torque, usually that of a spring. In nearly all wattmeters the current coil is made the fixed coil because the current in it is ordinarily too great to be carried by the springs. In most cases the fixed coils surround the moving coil.

Current and Voltage Ranges of Wattmeters. It was formerly customary to construct portable wattmeters for currents up to 200 to 400 amp, but the present tendency is to avoid such high current ranges. It is very difficult to construct a 200-amp current coil so that the distribution of an alternating current over the cross-section of the coil will be accurately identical (as to production of torque) with the distribution of the direct current with which the wattmeter must be checked. Also, as the current range is made greater, it becomes increasingly difficult to guard against errors occasioned by stray field from the current leads to the wattmeter. Recent great improvements in the ratio and phase-angle accuracy of current transformers make it possible to obtain better accuracy from a 5-amp wattmeter and a current transformer than from a wattmeter of large current rating connected directly in the line. However, when a wattmeter is to be used to measure the total power in an a-c circuit in which flows a d-c component, the current transformer cannot be used. Although single-phase switchboard wattmeters are made for currents up to 400 amp, there is a recent tendency to restrict the current range to 20 amp or less.

Wattmeters are relatively expensive instruments, and when they are used to check portable standard watthour meters the accuracy of their indications is of great commercial importance. It is therefore usual to build portable wattmeters with two current ranges and with two (sometimes three) voltage ranges, thus facilitating the obtaining of the largest possible deflection for the amount of power under measurement. Abroad, wattmeters are frequently made with three current ranges in the ratio 1 : 2 : 4, and as an extreme case, with six current ranges, which, however, are obtained at a sacrifice of 50 per cent in torque.

A **polyphase wattmeter** contains two single-phase wattmeter mechanisms with the moving coils attached to a common shaft. Its use makes it possible to measure power in two-phase or three-phase three-wire circuits with a single instrument.

Methods of Connecting Wattmeter in Circuit; Correction for Power Loss in Wattmeter. A wattmeter may be connected to the load which it is to measure in either of

the two ways illustrated in Figs. 24 and 25. When connected as in Fig. 24 the current through the current circuit of the wattmeter is equal to the vector sum of the current in the load and that in the voltage circuit of the wattmeter; hence the wattmeter will read the sum of the watts in the load and the watts loss in the voltage circuit, which is equal to E^2/R_p, where R_p is the resistance of the voltage circuit and E the voltage across the load. For precise work this correction should always be made, unless the wattmeter is of relatively high current range or is "compensated"; see below.

In the second scheme of connection, Fig. 25, the current through the current circuit is the same as that taken by the load, but the voltage across the voltage circuit of the wattmeter is higher than the voltage across the load by the drop through the wattmeter current coil, and the wattmeter reads too high by an amount equal to the loss in this coil. This loss in equal to $R_c I^2$, where R_c is the resistance of the current circuit and I the load current; it is usually less than the loss in the voltage circuit, hence if no correction is made for the wattmeter loss the scheme of connections shown in Fig. 25 should be used. If the highest accuracy is required, especially with a wattmeter of low current rating, the connections shown in Fig. 24 should be used, and a correction should be applied.

When a voltmeter is connected to the load across AA' in Fig. 24, while the wattmeter reading is being taken, a correction may need to be made for the power taken by the voltmeter. Calling R_v the resistance of the voltmeter and multiplier, if any, and E the voltage across the load, the loss in the voltmeter is E^2/R_v. In most cases the voltage-circuit losses in the wattmeter and voltmeter are best determined by a direct measurement with the wattmeter, using the test voltage and leaving the load circuit open. If the voltmeter is connected across BB' in Fig. 25, the power loss in it is not read by the

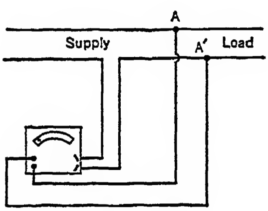

Fig. 24

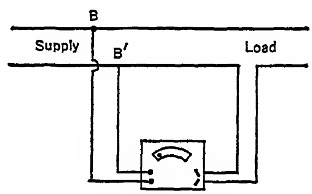

Fig. 25

wattmeter, and the voltmeter reading equals the load voltage plus the impedance drop in the wattmeter current coil.

Compensation for Loss in Voltage Circuit of Wattmeter. In the so-called compensated wattmeters a stationary compensating coil, in series with the moving coil, is placed so that the current through it produces on the moving coil a torque equal and opposite to that produced by this same current flowing through the current coil. To make this compensation accurate for all positions of the moving coil, the compensating coil must be intermingled with the current coil. A compensated wattmeter should always be connected to the circuit, as shown in Fig. 24; when so connected no correction for the loss in the wattmeter is necessary. As a check on the correctness of connections, the load circuit may be opened, whereupon the wattmeter reading should be zero.

Phase Angle of Voltage Circuit of a Wattmeter. The inductance of the moving coil of a simple (uncompensated) wattmeter tends to cause the alternating current in the voltage circuit to lag slightly behind the impressed voltage. Distributed capacitance in the series resistor tends to counteract this tendency, but only slightly in the flat-card resistors now generally used. The resultant lag of the current is known as the phase angle α of the wattmeter. It is usually about 2 to 4 minutes (at 60 cycles) in high-grade wattmeters of the deflection type having a voltage circuit rated at 125 to 150 volts; for the Westinghouse precision wattmeter, 150-volt range, it is about 12 minutes; it varies directly as the frequency and inversely as the voltage rating. The error which it introduces into the measurement of a-c power becomes relatively greater as the power factor is lowered. The angle α is taken as positive when the positive reactance of the wattmeter moving coil predominates over any negative (capacitive) reactance in the voltage circuit. Such a wattmeter will give a larger reading on an inductive load than on a non-inductive load, for the same actual power.

Effect of Mutual Inductance on Wattmeter Reading. In most wattmeters of the deflection type the mutual inductance between the fixed coils and the moving coil changes sign at approximately half-scale deflection. For any other relative position of the coils there is an error caused by mutual inductance which is negligible in good wattmeters

of current ratings of 5 amp or more and voltage ratings of 75 volts or over, used with ordinary power frequencies. For higher frequencies, lower current ranges, or lower voltage ranges it may be advisable to check the magnitude of the mutual-inductance error; formulas for this purpose are given in *Trans. A.I.E.E.*, vol. 39, pp. 563-567, 1920.

Effect of Eddy Currents on Wattmeter Reading. Eddy currents in fixed conducting masses near the fixed coils will set up magnetic fluxes which combine with the flux of the current coil to form a resultant flux which differs from that of the current coil in both magnitude and phase. There is no simple way to correct for the resulting error, and it is up to the maker to use as little metal as possible, and that of high resistivity, and to arrange it in such a way as to minimize the presence of closed paths for eddy currents. Appreciable eddy-current errors resulted in one case from the inadvertent omission of insulating washers in a metal assembly holding the field coils. In another, short-circuited turns in the compensating winding caused a similar result. One or more short-circuited turns in a current coil would produce the same kind of result but to a greater extent, but such a condition should be revealed by its effect on the d-c performance of the wattmeter.

Compensation for Inductance of Voltage Circuit of Wattmeter. The phase angle of a wattmeter may be reduced to zero (that is, the inductance of its voltage circuit may be compensated) by shunting a capacitor of capacitance C around a portion R/n of the series resistance of the voltage circuit. If the inductance of the voltage circuit is L, the relation which gives compensation of phase angle is

$$C = \frac{Ln^2}{R^2} \tag{7}$$

The practical application of this formula requires precautions which are summarized in *Trans. A.I.E.E.*, vol. 39, pp. 562-563, 1920.

Correction Factor for Self-inductance of the Voltage Circuit of a Wattmeter. If a wattmeter is used to measure the power of a sinusoidal current I which lags by an angle θ behind the emf E, and if the inductance and resistance of the wattmeter voltage circuit are L and R, so that $\tan \alpha = \omega L/R$ is the tangent of the angle of lag in the voltage circuit, the correction factor C by which the reading of the wattmeter must be multiplied to correct it for the effect of inductance in the voltage circuit is

$$C = \frac{1 + \tan^2 \alpha}{1 + \tan \alpha \tan \theta} \tag{8}$$

In a wattmeter which is fit to use, $\tan \alpha$ will be small and its square negligible. Consequently the term $\tan^2 \alpha$ may be omitted from the numerator. This formula becomes useless for power factors near zero, at which point $\tan \theta$ becomes infinite. To avoid this difficulty, **Drysdale** proposed an additive correction for the self-inductance of the voltage circuit. It is outlined, with numerical examples, in *Trans. A.I.E.E.*, vol. 39, pp. 560-562, 1920.

The tangent formula above given (eq. 8) has been much used in America in a form which is trigonometrically identical with it but in which the wattmeter phase angle α is extended to include also the phase displacements introduced by a current transformer and a voltage transformer.

Correction of Wattmeter Reading for Phase Angles of Wattmeter and of Instrument Transformers. Let α denote the phase angle of the wattmeter as above defined, β and γ the phase angles of the current transformer and the voltage transformer, respectively. Let P_2 denote the wattmeter reading corrected for scale error and multiplied by the product of the corrected ratios of the current and voltage transformers, E the voltmeter reading corrected for scale error and multiplied by the ratio of the voltage transformer, and I the ammeter reading corrected for scale error and multiplied by the corrected ratio of the current transformer. Then the apparent power factor is

$$\cos \theta_2 = \frac{P_2}{EI} \tag{9}$$

and the true power is

$$P = P_2 \frac{\cos (\theta_2 + \alpha + \beta - \gamma)}{\cos \theta_2} \tag{10}$$

The angle θ_2 is to be taken as positive when the current lags behind the voltage, and as negative when the current leads. In the case of β and γ a positive angle denotes that the reversed secondary quantity leads the primary quantity. Using this definition, formula (10) shows that a leading phase angle γ tends to offset the effect of a leading phase angle β. Values of the correction factor $\frac{\cos (\theta_2 + \alpha + \beta - \gamma)}{\cos \theta_2}$ are given in Tables I and II. Note carefully the conditions, stated at the head of each table, to which each

table applies. It should be noted that formula (10), like the tangent formula (8), becomes useless as the power factor of the load approaches zero.

Table I. Phase-Angle Correction Factors: for Lagging Current When ($\alpha + \beta - \gamma$) is Positive; for Leading Current When ($\alpha + \beta - \gamma$) is Negative.

Interpolation for correction factors corresponding to values of ($\alpha + \beta - \gamma$) lying between those given in the table may be made without error. Interpolation for correction factors corresponding to values of $\cos\theta_2$ lying between those given in the table may be made without exceeding an error of 0.0010 in the sections of the table lying between the heavy black lines; outside of these sections, and in all cases where the adjacent values of $\cos\theta_2$ are separated by the heavy black lines, the maximum error in interpolation will exceed 0.0010.

The above convention in regard to the algebraic sign of the phase angle γ of a voltage transformer (positive sign for secondary voltage *leading* the reversed primary voltage) is consistent with the universally adopted convention as to the sign of the phase angle of a current transformer; it has been used for many years by the National Bureau of Standards and by the principal foreign national laboratories, and was adopted in 1930 by the International Electrotechnical Commission. The opposite convention, namely, γ positive for secondary voltage *lagging* the reversed primary voltage, is still in use. When it is used, the correction factor becomes $\dfrac{\cos(\theta_2 + \alpha + \beta + \gamma)}{\cos\theta_2}$. In both of these forms of the correction factor the + and − signs in the numerator are addition (or subtraction) *operators*, and the angles α, β, and γ may be intrinsically either + or −. The angles α and β, however, are nearly always intrinsically positive. The following examples illustrate the use of the correction tables.

Example 1. Given a single-phase circuit with lagging current in which the wattmeter reading corrected for scale error and multiplied by the corrected ratios of current and

Interpolation for correction factors corresponding to values of $(\alpha + \beta - \gamma)$ lying between those given in the table may be made without error. Interpolation for correction factors corresponding to values of $\cos \theta_2$ lying between those given in the table may be made without exceeding an error of 0.0010 in the sections of the table lying between the heavy black lines; outside of these sections, and in all cases where the adjacent values of $\cos \theta_2$ are separated by the heavy black lines, the maximum error in interpolation will exceed 0.0010.

voltage transformers equals 24,520 watts, and the product of the voltmeter and ammeter readings, similarly corrected, equals 35,600 volt-amperes. Then $\cos \theta_2 = 24{,}520/35{,}600 = 0.689$. If the equivalent phase angle α of the wattmeter is $+ 4'$ and if from examination of characteristic curves the current-transformer phase angle is found to be $+ 48'$ and the voltage-transformer phase angle is $+ 10'$, then $\alpha + \beta - \gamma = + 42'$, and from Table I, the correction factor is 0.9871. Whence the true power equals $24{,}520 \times 0.9871 = 24{,}204$ watts.

Example 2. Given a single-phase circuit with leading current, in which the wattmeter reading, corrected as in example No. 1, equals 12,266 watts and the product of the voltmeter and ammeter readings, similarly corrected, equals 24,532 volt-amperes. Then $\cos \theta_2 = 12{,}266/24{,}532 = 0.5$. If the equivalent phase angle α of the wattmeter is $+ 5'$, the phase angle β of the current transformer $+ 2° 33'$ and the phase angle γ of the voltage transformer is $- 38'$, then $\alpha + \beta - \gamma = + 3° 16'$ and therefore from Table II the correction factor to be used is 1.0971. Whence the true power equals $12{,}266 \times 1.0971 = 13{,}457$ watts.

In measuring badly unbalanced three-phase loads with two wattmeters, corrections should be applied separately, as above, to each wattmeter. When the circuit is balanced a single correction based on $\cos \theta_2$ for the whole circuit may be used.

Accuracy of Wattmeters. High-grade portable wattmeters have a stated accuracy of 0.2 to 0.25 per cent of full-scale value for single-phase or 0.5 per cent for polyphase wattmeters. It is not practicable to obtain as high accuracy in the latter, on account of the impossibility of making both elements of the polyphase wattmeter follow exactly the same scale law. This theoretical disadvantage of the polyphase wattmeter is offset by its greater convenience and the reduction in number of observations necessary. High-grade switchboard wattmeters have a stated accuracy of 1 per cent of full-scale value. Laboratory standard wattmetters have a stated accuracy of 0.1 per cent of full-scale value.

Wattmeters are usually tested for accuracy on direct current, using a potentiometer and suitable accessories. For convenience in computing the values of watts, a voltage of 100 volts may be used for wattmeters for use on 110-volt circuits. The current required to produce a given deflection having been recorded, a second observation is made after reversing the currents in both of the windings of the wattmeter. The mean of two such readings which do not differ more than several per cent is free from error due to stray magnetic field in unshielded wattmeters, or from accidental magnetic polarity in the iron shield of shielded wattmeters, such as may arise from an accidental large overload in the current coil. This test on "reversed direct current" having been made at a sufficient number of points on the scale, it is necessary, for a new wattmeter, and advisable for one that has been in service for some time, to determine the difference between the a-c power and the d-c power required to produce a given deflection. For this test another wattmeter must be used, of known or calculable a-c performance. This test may be made only at power factor 0.5, for wattmeters of proved construction, but for a new design the test should be made at zero power factor also.

Measurement of Three-Phase Power. The measurement of the power supplied to a three-phase load may be effected in one or more of the following ways. The connections may be made either directly or through proper instrument transformers.

Single-element Wattmeter on Three-wire Three-phase Load. The current circuit of the wattmeter is connected in series with one of the mains supplying the load, and the voltage circuit of the wattmeter is connected between the corresponding terminal of the load and the neutral. If the neutral point of the load, or of the transformers supplying the load, is not available, a "Y-box" (see below) can be used to establish an artificial neutral. If the load is perfectly balanced the power input is then three times the wattmeter reading. However, a three-phase load is seldom sufficiently well balanced, even in the case of a three-phase motor load, to render this method of measurement an accurate one.

Y-box. The simplest form of Y-box consists of two equal non-inductive resistors connected in series, each of the free ends and the junction point being connected to a binding post. Each resistor has a resistance equal to that of the voltage circuit of the wattmeter. One terminal of the voltage circuit of the wattmeter is connected to the junction terminal of the Y-box and the other terminal of the voltage circuit to the line wire in which the current circuit of the wattmeter is connected. The other two terminals of the Y-box are connected to the other two line wires, respectively.

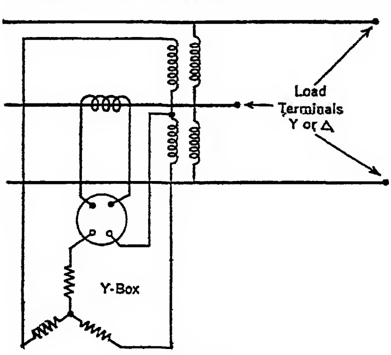

FIG. 26

In the case of wattmeters designed especially for use with a Y-box, part of the resistance of the potential circuit of the wattmeter is placed in the Y-box, being connected permanently to the junction point between the other two resistors. A similar arrangement may be used as a multiplier. The connections of such a Y-box, wattmeter, and instrument transformers are shown diagrammatically in Fig. 26.

Two-wattmeter Method for a Three-wire Three-phase Load. The simple arrangement of two wattmeters shown in Fig. 27 will give exactly the total power in any three-wire circuit, provided each wattmeter by itself gives accurate indications. Aside from the sources of error, as noted above, which may affect the accuracy of a wattmeter on a single-phase circuit, the arrangement shown in Fig. 27 will give the true power for any condition of unbalancing, wave form, frequency, etc. It is also immaterial whether the load be Y or Δ connected. The connections may be made directly as shown or through two current transformers and two voltage transformers, the connections in the latter

case being the same as in Fig. 28 except that two separate wattmeters instead of a polyphase wattmeter are used.

Rule for Adding or Subtracting Readings. With the arrangement shown in Fig. 27 the total power is always the *algebraic* sum of the readings of the two wattmeters. Since a wattmeter reads in only one direction, usually to the right, the two instruments must be so connected to the line that the needle of each instrument is deflected over the scale. For a balanced three-phase load having a power factor greater than 50 per cent, the sum of the two wattmeter readings, when the connections are thus made, gives the total power; for a power factor less than 50 per cent the difference of the two readings must be taken. When the power factor is not known, one can determine whether the sum or the difference of the readings should be taken by interchanging the two wattmeters, leaving unaltered the potential connections to the third wire (C in Fig. 27); if the pointers of the two wattmeters deflect in the same direction as before, add the two readings; if one of the pointers deflects in the opposite direction (i.e., against the stop), take the difference. In making this test, care must be exercised to connect the source side of each of the two lines (in which the current coil of each wattmeter is connected in succession) to the same binding post of the given wattmeter in each of the two positions.

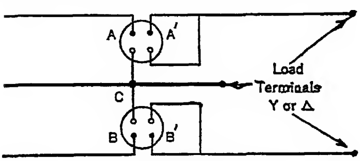

Fig. 27

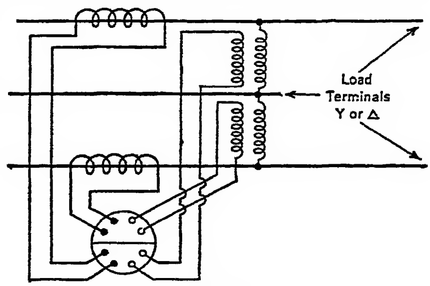

Fig. 28

When the load is balanced, and the two wattmeters are connected, as in Fig. 27, so that each gives a positive reading, the question as to whether the power factor is above or below 50 per cent can be determined by changing the potential lead of the lower-reading wattmeter from the common connection C to the line in which the current coil of the other wattmeter is connected. If the reading thus obtained is positive, the power factor is more than 50 per cent and the readings should be added; if the reading is negative the power factor is less than 50 per cent and the readings should be subtracted.

When three wattmeters are used for the measurement of a three-phase four-wire load they should be connected in a manner similar to that used for two wattmeters on a three-wire system, i.e., each of the three voltage circuits should be connected between a main wire and the neutral wire, and each of the three current circuits should be connected in series with the corresponding main wire.

Special Precautions in Use of Wattmeters. In addition to the general precautions given under the heading "Precautions in Placing and Using Instruments," the following special points must be noted. A wattmeter has three distinct limits, namely, current, voltage, and power, no one of which should be exceeded. The potential of the moving coil must not be greatly different from that of the fixed coil, and the connections must always be such as to ensure this condition, both in the use and in the checking of a wattmeter. This precaution is especially necessary when an external multiplier is used for high voltages. Unshielded wattmeters, not of astatic construction, are very susceptible to the effect of stray magnetic field because of the relatively weak operating field of the current in the current coil. In using such wattmeters, special care should be taken to locate them where this effect will be negligible. To check this point, allow current to flow in the voltage circuit only. Any deflection will then be due to stray field. In applying this test to a wattmeter with more than one current range which is compensated for the loss in its voltage circuit, the switch for changing the compensating-coil connections (as the current range is varied) must be correctly set, or an error will result. To minimize stray-field error, in wattmeters of the deflection type, it is the practice of American makers to surround the wattmeter coils with a laminated magnetic shield.

FREQUENCY METERS. Indicating frequency meters have been made in a great variety of types, of which relatively few are now used in American practice. The following may be mentioned.

In the vibrating-reed frequency meter a number of thin steel reeds, tuned to respond to a closely graded series of frequencies, are mounted so that their free ends are aligned

with a scale marked in cycles per second. An electromagnet is arranged to act upon the reeds, either directly or by vibrating a common frame supporting all the reeds. The electromagnet is so designed that the normal line voltage will produce such moderate forces on the reeds that only those reeds with frequencies very close to the line frequency will respond. The ends of the reeds are provided with white flags which appear to widen as the amplitude of vibration increases. Frequency meters of this type cannot be read as closely as those of the pointer type, but they have some advantages which make them valuable, especially for use in the laboratory. These are as follows: The indications being dependent on the fundamental frequency, the effect of distortion of the voltage wave is very small. The indications are not influenced by moderate changes of voltage; nevertheless, extreme changes must be avoided. The indications are only very slightly dependent on the temperature of the reeds, the change in frequency being 0.01 per cent per degree centigrade. An increase of temperature reduces the normal frequency of the reeds, that is, causes the indicated frequency to be too high. Vibrating-reed frequency meters must be protected from intense mechanical vibrations.

In American practice the vibrating-reed frequency meter has been restricted to laboratory uses. For use on switchboards some form of indicating frequency meter has always been preferred. Frequency meters of the induction type (Westinghouse), the resistance-reactance type (General Electric), and the bridge type (Weston) have been superseded in recent years by modern types capable of the greater sensitivity and accuracy demanded by present-day practices, including system interconnection and the operation of synchronous-motor clocks.

The **tuned-circuit frequency meter** resembles the earlier pointer-type frequency meters but may be made much more sensitive and much less susceptible to error from variation of wave form because the tuned circuits act as filters to pass only the fundamental. The extreme sensitiveness obtainable is shown by the fact that switchboard frequency meters are made by the General Electric Co. in which the entire length of the scale corresponds to the range 59.5-60.5 cycles. Even narrower ranges would be possible under this principle of construction, the practical limitations arising from the temperature coefficient and other minor changes in the available capacitors. The **General Electric frequency meter** has a pair of coaxial fixed coils which are composed of two equal interwound windings of opposite polarity. There is a single moving winding which carries the sum of the currents in the two fixed windings. The torque depends upon the product of the vector sum of the two currents by their vector difference, and changes greatly for a small change in the relative value of the two currents. To make the instrument indicate frequency, a control is necessary; and to make the indications independent of the line voltage this control must vary as the square of the line voltage. Such a control is realized by the addition to the moving element of a nickel-iron-alloy vane which tends to align itself with the field of the fixed coils.

The **Westinghouse resonance-type frequency meter** (Fig. 29) consists of a pair of stationary field coils within which rotate two moving coils fixed on a common shaft at right angles with each other. A reactor 8 is connected in series with the fixed coils, and a capacitor 10 is shunted across the fixed coils and the moving coil 3. The relation between capacitance and inductance is such that parallel-circuit resonance occurs at the normal frequency. The moving coil 2 is connected in series with the parallel-resonance circuit. There is no mechanical control of the moving system, which assumes a position depending on the relation between the forces set up by the currents in the coils. The sensitivity to frequency changes is such that a range of 58 to 62 cycles is obtainable for use on 60-cycle systems. The resonant circuit employed makes the instrument very insensitive to temperature changes and keeps the burden down to a low figure, namely, 3.2 volt-amperes at 110 volts, 60 cycles.

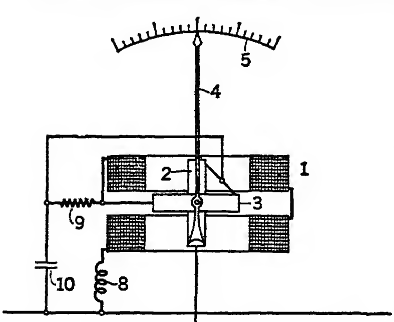

FIG. 29

The **Weston frequency meter** is of the moving-iron type. Two fixed coils mounted at right angles to each other act upon a single iron needle carried by a shaft which also carries the pointer and a damping vane. There is no spring or other mechanical control. The connections are shown in Fig. 30. Current from the upper line wire passes through the reactor X_1, resistor R, and field coils 1; at the junction point P_1 the current divides

into two components mutually displaced in phase, namely, a lagging component through field coils 2 and reactor X, and a leading component through capacitor C. At the junction point P_2 these components unite and flow through reactor X_2 to the lower line wire.

The undivided current in coils 1 produces a magnetic field tending to displace the needle from the central position in which it is shown and which corresponds to the normal operating frequency. The lagging component of current flowing through coils 2 tends to hold the needle in its central position. At normal frequency the effect of the fundamental of this current is very great because the circuit 2, X, C becomes resonant. For lower frequencies the lagging component of the current in coils 1 preponderates because of the decrease in the reactance of X, and the increase in the reactance of C, and the needle is deflected to the left. The converse effect takes place when the frequency exceeds the normal value. The reactors X_1, X_2, are used only when the wave form of the line voltage is very much distorted. For ordinary commercial wave forms the action of the resonant circuit in responding selectively to the fundamental makes the accuracy of indication independent of the wave form.

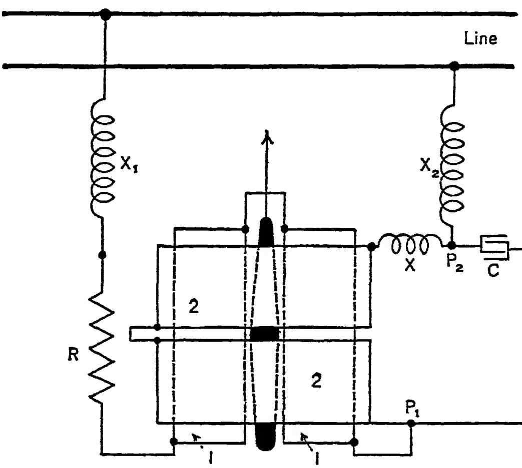

Fig. 30

The **Leeds & Northrup frequency recorder** records and indicates the frequency. It contains a bridge network connected to the line voltage. Two arms are resistors, a third is a capacitor shunted by a resistor, and the fourth is a capacitor in series with a resistor. Sliding contacts, actuated by the auxiliary motor of the recorder in accordance with the position of the galvanometer pointer, move with a change of frequency until a balance of the bridge is re-established. This instrument is very sensitive to changes of frequency and very insensitive to changes of temperature and line voltage. In one 60-cycle recorder the pen traverses the 10-in. chart for the change from 58 to 62 cycles, and in another for the change from 59 to 61 cycles.

POWER-FACTOR METERS. The phase relation between the current and the voltage in a circuit or a polyphase system can be measured by indicating instruments of a type in which the mechanical angle between the instrument pointer and a reference mark is equal to the electrical phase angle between current and voltage. If the scale is graduated in equal angular intervals the instrument is called a **phase meter.** If the scale is graduated according to the cosine of the phase angle, the instrument is called a **power-factor meter.** If the graduations are marked according to the sine of the phase angle it is called a **reactive-factor meter.**

Strictly speaking, the power factor as defined for single-phase systems is the quotient obtained by dividing the power by the product of the effective values of the voltage and the current. The power factor may therefore be computed directly from the readings of a wattmeter, a voltmeter, and an ammeter, but if the wave forms are not sinusoidal the power factor will not be measured exactly by an instrument whose indication depends only on phase displacement.

For a polyphase system the power factor has been defined by arbitrary convention as the ratio of the total power to the total vector volt-amperes, the total vector volt-amperes, in turn, being defined as the square root of the sum of the squares of the total active power and the total reactive power. For sine waves this definition is consistent with that for the single-phase case, but for non-sinusoidal wave forms the polyphase definition is theoretically inconsistent with any logical generalization of the single-phase definition.

Power-factor meters of the indicating type depend for their operation on the interaction of a pulsating single-phase magnetic field, produced by a single coil, and a rotating magnetic field produced by two or more other coils, which are so placed that the mechan-

ical (space) angle between their axes is equal to the electrical (time-phase) angle between the currents in them. The actual moving element may be either the single coil or the two or more other coils mentioned, or an iron vane magnetized by the single coil. In any event, the moving element will take up a position such that at the instant the pulsating field has its maximum value the rotating field has the same direction as that of the pulsating field.

In all types of these instruments the moving element is intended to be free from all mechanical constraint and hence on open circuit it will point indifferently in any direction. Because of the relatively weak electrical restoring torque, the indication becomes definite only when the product of the applied current and voltage is at least half the normal value.

In instruments for use on single-phase circuits the rotating magnetic field is obtained (usually from the voltage circuit) by supplying one coil through a non-inductive resistance while the other is in series with a highly inductive iron-cored reactance coil. When used on polyphase circuits the rotating field can be obtained more easily (usually from the voltage circuits) by using a non-inductive resistor in series with each of the two or three coils spaced 120 deg apart which produce the rotating field. If a single current coil connected in series with one line is used, the instrument reading will depend only on the phase displacement between that current and the corresponding star voltage, and will correctly represent the entire polyphase load only if this is balanced. An instrument having three such elements will correctly indicate the polyphase power factor even on an unbalanced load if the wave form is sinusoidal.

Some instruments, especially those of the magnetic-vane type, are provided with a scale covering the complete 360 deg and serve to indicate the direction of flow of power as well as the phase relation of current to voltage.

REACTIVE-POWER METERS. These instruments, also called reactive-volt-ampere meters or reactive-component meters, are essentially wattmeters so connected in an a-c line as to make the voltage across the voltage circuit (or circuits) of the instrument 90 deg out of phase with the voltage which would be applied in the case of power measurement. If a polyphase reactive-power meter is connected in circuit so that the shift of phase is obtained by suitable connections to the secondary terminals of ordinary voltage transformers, the indication in watts which the instrument would give if connected as wattmeter must be multiplied by a suitable factor (which depends on the connection used) to obtain the reactive power in "vars." (At the meeting of the International Electrotechnical Commission in Oslo in 1930 it was voted to adopt "the name or term var for designating the unit of reactive power"; i.e., 1 var results from 1 volt acting in quadrature with 1 amp). If special voltage transformers, or if auto-transformers connected to the secondary of the voltage transformers, are used, the correction factor can be automatically allowed for and the meter will read directly in vars.

Any reactive-power measuring device which depends on cross-connection of the voltage circuits will read incorrectly if both the voltages and the currents are unbalanced. Those in which the number of current coils is less by two than the number of wires in the circuit will be incorrect on unbalanced currents, even if the voltages are symmetrical.

SYNCHROSCOPES. A synchroscope is essentially a robust form of phase meter in which the pointer is free to rotate. It is provided with a single scale mark which denotes synchronism, that is, equality of frequency and coincidence of phase of two a-c sources. In use, one of the two windings is connected to the bus, the other to a machine which is to be connected to the bus. Synchroscopes have superseded, in great measure, the various forms of synchronizing devices employing lamps.

In the General Electric synchroscope two split-phase windings are located on an iron core arranged to rotate. The windings are connected through slip rings to the incoming machine, and the phase displacement is obtained by a reactor in one winding and a resistor in the other. A stator surrounding the rotor has its windings connected to the bus. When exact synchronism is reached, a pointer attached to the rotor shaft remains at rest in a vertical position. The synchroscope is usually connected through voltage transformers; on polyphase circuits only one phase is used.

In the Westinghouse synchroscope an iron vane, free to rotate, is magnetized by a fixed coil connected to the incoming machine. The vane is located within a rotating field produced by current from the bus passing through two coils which are fixed at approximately right angles with each other. A reactor in series with one of the coils and a resistor in series with the other produce a phase displacement between the two currents. The pointer attached to the rotating vane indicates at any moment the phase displacement between the voltages of the bus and the incoming machine, and the speed and direction of its rotation depend on the difference between the two frequencies.

The Weston synchroscope consists of an instrument mechanism similar to that of an electrodynamic voltmeter. The fixed winding is connected to the bus through a

resistor, and the moving coil is connected to the incoming machine through a capacitor. When the voltage of the incoming machine is either in phase with or in opposition to the bus voltage no torque is exerted on the moving coil and the pointer stands in its central (vertical) position. For any other phase relation the pointer will be deflected to the right or to the left, when the incoming machine is ahead or behind, respectively. The pointer is behind a translucent screen, and only its shadow, cast by a synchronizing lamp, can be seen. This lamp is operated by a double-primary transformer connected for synchronizing "light." When the shadow of the pointer is in the vertical position, the incoming machine is in phase. The pointer will be vertical for phase opposition also, but cannot be seen then because for this condition the synchronizing lamp is dark. When the incoming machine is too fast or too slow a succession of shadows of the pointer will be seen, and the shadow will appear to rotate in the clockwise or counter-clockwise direction, respectively.

INSTRUMENTS FOR MEASURING RECTIFIED CURRENTS. A rectified current will not give identical indications when measured with ammeters of various types. A rectified current may be regarded as equivalent to the superposition of a direct current upon an alternating current. The proper type of ammeter to use depends entirely upon the function to be performed by the rectified current. For charging storage batteries or for electroplating, the desired result is proportional to the d-c component of the rectified current, and a permanent-magnet moving-coil instrument should be used because it responds only to this component. For rough measurements the less expensive polarized-vane instrument may be used if it has been calibrated for use on the particular wave form. If the rectified current is used for incandescent lamps or for electric heating devices, its effective (rms) value is significant, and ammeters of either the electrodynamic type or the electrothermic type will theoretically give the correct value for the given purpose. Electrodynamic and electrothermic ammeters, however, are not generally available, which makes it desirable to measure the effective value of rectified currents with a moving-iron ammeter of good quality if an accuracy of, say, 1 or 2 per cent is sufficient. If the wave form of the rectified current is very much distorted in comparison with a half-cycle of a sinusoidal current, or if doubt exists as to the quality of the design of the moving-iron ammeter and the magnetic material used in it, the ammeter should be checked on the given current against an electrodynamic or electrothermic ammeter.

When the rectified current is used to operate an arc lamp and is to be adjusted to produce the same light output as would be given by a stated direct current, the permanent-magnet moving-coil ammeter gives approximately correct results and is the only kind to be used. However, its indications will usually be very erroneous as regards the heating effect of the current in the carbons, the rheostats, cables, etc., and if overheating is to be avoided, a moving-iron ammeter should also be in circuit. This precaution is needed also in using rectified currents for battery charging and electroplating.

For a full description of the measurement of rectified currents for various purposes, see paper by W. N. Goodwin, Jr. (Bibliography).

The choice of a voltmeter for voltage measurements with rectified currents is based on the preceding considerations for the ammeter. For battery charging or electroplating, a permanent-magnet moving-coil voltmeter should be used; for regulating the voltage applied to incandescent lamps, an electrodynamic, electrothermic, or (with reservations as for the ammeter) a moving-iron voltmeter; the product of the effective voltage, so measured, by the effective current will give the watts only if the circuit is non-reactive. If reactance is present the power must be measured with a wattmeter.

The a-c component of a rectified current may be measured by a "selective ammeter" if the d-c component is 5 times the a-c component, or less. This instrument is of the iron-core electrodynamic type and has a self-contained current transformer with an air gap in its magnetic circuit.

OHMMETERS. The name "ohmmeter" is applied to two radically different types of portable instrument for the rapid and simple measurement of resistance with moderate accuracy. One of these is a simplified Wheatstone bridge and the other is essentially a voltmeter with an ohm scale. The Roller-Smith ohmmeters are slide-wire bridges. They are built in three forms. Self-contained batteries are the source of current in each case. In two forms a built-in galvanometer is the only detector provided. In the third form either a galvanometer or a telephone receiver may be used as the detector, and the battery may be used either as a d-c source or to operate an induction coil, the primary of which may be used as an a-c source. This latter ohmmeter serves for the usual resistance measurements; for the measurement of inductance, capacitance, and resistivity of electrolytes; and also for fault location.

In the **Leeds & Northrup d-c ohmmeter** the slide wire is mounted within the instrument on the edge of a circular disk which may be rotated by means of a handle above the

panel. A d-c galvanometer and a battery are mounted within the case. The **Leeds & Northrup a-c ohmmeter** closely resembles the d-c ohmmeter but has an a-c galvanometer and an insulating transformer. In the ordinary applications of these ohmmeters any one of five built-in standard resistors may be used, according to the magnitude of the resistance under measurement. Provision is also made for an external standard, such as a copper coil, against which nominally like coils are to be checked. In this case the scale reads the ratio of the resistance of the unknown coil to that of the known coil.

Permanent-magnet moving-coil ohmmeters are made in various types which differ somewhat radically in principle of operation, including: volt-ohmmeters, ohmmeters with differentially wound moving coil, and quotient-type ohmmeters.

Volt-ohmmeters differ from ordinary voltmeters mainly in having an extra scale figured in ohms. It is usual to have the full-scale value of voltage coincide with the zero of the ohm scale. In use, a battery of such voltage as to give full-scale deflection is connected to the instrument; if the unknown resistance be now introduced into the circuit, the pointer will drop back to a position corresponding to the reduced value of the current, when the resistance may be read off directly from the ohm scale. As it is obviously difficult to ensure that an available battery will produce exactly full-scale deflection, the more accurate instruments of this type, intended only for use as ohmmeters, have an adjustment, usually a magnetic shunt, by which the pointer may be brought to the full-scale mark in spite of normal variation of the battery voltage.

Any **d-c voltmeter may be used as an ohmmeter** in connection with a constant-voltage source. If the deflection is d_1 with the voltmeter connected directly to the source, and d_2 with the unknown resistance x in series with the voltmeter, the unknown resistance is given by the relation

$$x = \left(\frac{d_1}{d_2} - 1\right) r \tag{11}$$

where r is the resistance of the voltmeter.

Ohmmeters with differentially wound moving coil are exemplified by the Weston Model 1 direct-reading ohmmeter. This permanent-magnet moving-coil instrument has two windings in the moving coil, the effect of the current in one winding being to deflect the pointer up scale and that of the other to deflect it down scale. Suitable resistances in the instrument, controlled by a plug switch, provide for three ranges, for example, 0-200, 0-1000, and 1000-2000 ohms. To take care of variations in battery voltage, a magnetic shunt is adjusted to bring the pointer to the full-scale mark with no connection between the X posts and with the plug in the checking position.

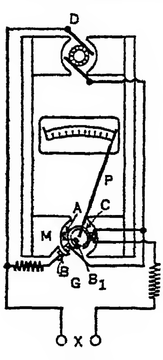

Fig. 31

The **quotient-type ohmmeter**, in principle, is independent of the value of the battery voltage because its indication depends upon the ratio of two oppositely directed turning moments produced by currents flowing in two coils. One of these coils is in a circuit of fixed resistance; the other contains the resistance under measurement. A change of the voltage changes both the currents but does not alter their ratio. The **Evershed megger** is an ohmmeter of the quotient type, intended principally for measuring relatively high resistances in megohms, whence the name. Its construction is indicated diagrammatically in Fig. 31 in which D is a small hand-driven d-c magneto and G a special form of moving-coil instrument. One pair of bar magnets supplies the flux for both. The galvanometer contains three coils rigidly attached at a fixed angular distance apart to the shaft which carries the pointer P. The unknown resistance is connected at X.

The coils BB_1, called the pressure coils, are permanently connected through a resistance across the terminals of D. The current coil A is made to move through an annular gap in such a manner that the field in which it moves is uniform, whereas the pressure coils BB_1 move from a position midway between the poles, where the field is at a minimum, into a stronger field, the connections being such that the torque due to the current in the current coil is opposed by the torque due to the current in the pressure coil. With no current in the current coil, that is to say, when the resistance to be measured is infinite, current through the pressure coils will cause them to come to rest with their plane at right angles to the magnetic field. When the current through the current coil is increased by putting in lower resistances, the current coil drags the moving system round in a clockwise direction; since the pressure coils come into a stronger and stronger field, the resistance to this motion becomes greater and greater. Hence a definite position is assumed by the system for the particular resistance at X. An increase in voltage would

increase the current in both current and pressure coils in the same proportion; consequently the instrument is independent of the voltage of the generator.

In the less-expensive meggers the generator gives a variable voltage depending upon the speed of rotation of the handle. In higher-priced meggers the generator is driven through a slipping clutch to give a constant voltage for a considerable range in the speed of driving. The voltage at which an insulation test is made is often of some importance. Constant-voltage meggers are especially useful for testing insulation resistance associated with a large capacitance, where a varying test voltage would cause charging and discharging currents to flow with resulting fluctuations in the readings.

Meggers are made with generators giving a maximum of 2500 volts and with a maximum measurement range of 4 to 10,000 megohms. The successful operation of these instruments to measure such high values of resistance is possible because the Price guard-wire scheme is used to prevent leakage of current across and through insulating supports. Meggers may be checked for accuracy, using known resistances having only a small fraction of the full-scale value; see Bibliography, Ohmmeters, paper by H. B. Brooks.

The most recent form of megger is of particular interest to instrument designers and users because its small size and light weight (3 lb) are obtained by the use of modern magnetic alloy for the permanent magnets of the 500-volt generator and of the ohmmeter.

MICROFARADMETERS. Direct-reading pointer instruments for capacitance measurements are made by a number of manufacturers under the names of condenser meters, capacitance meters, and microfaradmeters. They are usually made to be operated by alternating current from ordinary lighting circuits. For details as to their operating principles and internal circuits, see reference under Microfaradmeters in Bibliography.

FLUXMETERS. The Grassot fluxmeter is essentially a moving-coil galvanometer, the suspension fiber of which exerts a negligible torque on the moving system. The motion of the coil is very heavily overdamped. Fig. 32 is a diagram showing its construction. The coil *C* swings in a uniform field in the air gap between the pole pieces *NS* of a permanent magnet and the soft-iron core *A*. The system is supported at the top by a single cocoon fiber, the upper end of this fiber being attached to a flat spiral spring *R*, to minimize the effect of shocks. The torsional force exerted by such a fiber is extremely small. S and S_1 are very thin silver strips, serving to lead the current to and from the coil *C*. These strips are in the form of springs, which, however, are extremely weak and exert the minimum practicable torque on the coil. An index attached to the coil swings over a calibrated scale. The fluxmeter is also provided with a mirror in addition to the pointer so that it may be used in conjunction with a lamp and scale or with a telescope and scale.

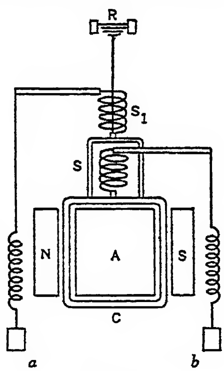

Fig. 32

When a given quantity of electricity is discharged through the moving coil, for example, by changing the flux threading an exploring coil connected to the terminals *a* and *b*, a force is exerted upon the coil tending to deflect it. The only opposing forces (neglecting the small torsional forces) are the mechanical friction to motion and the back emf induced in the coil by its motion through the field of the permanent magnet. The back emf is proportional at any instant to the velocity of the coil, and the frictional force is also approximately proportional to this velocity. If both forces are directly proportional to the velocity, when a given quantity of electricity is discharged through the circuit, the coil comes to rest at a definite point, depending only upon its initial or "zero" position and the total quantity discharged through it. As the quantity of electricity discharged through an exploring coil, when the magnetic flux threading it is changed, is proportional to the change in flux, the instrument can be calibrated to read directly the change in the flux produced in the region occupied by the coil. In practice the friction is not exactly proportional to the velocity, and the fiber and leading-in strips usually exert an appreciable force on the coil. The instrument therefore has not proved altogether satisfactory.

In motor or in dynamo work an exploring coil, consisting of one or more turns of wire, may be fixed or wound in position and the change in flux of induction observed on exciting the field magnet. Even in the largest work, where some minutes may be taken to reach the limit of magnetization, no serious error is thus introduced. The fluxmeter can also be used for the measurement of magnetic field strength, pole strength, and the distribution of magnetism in bar magnets. It is also adapted to the measurement of permeability and hysteresis.

PROTECTION OF INSTRUMENT MECHANISM FROM STRAY MAGNETIC FIELD. Because of the low reluctance of iron as compared with that of air, a soft-iron shield placed around the instrument mechanism will greatly reduce the disturbing effect of an external magnetic field on the reading of an instrument. Many types of switchboard and portable instruments are thus shielded. Permanent-magnet moving-coil instruments are not seriously affected except by relatively strong external fields, and ordinarily do not need shielding other than that afforded by the iron case used with switchboard instruments.

The modern high-permeability nickel-iron alloys, such as permalloy C and mumetal, are very suitable for use as magnetic shields. Using them, a given degree of shielding ratio can be obtained with very much thinner and lighter shields than when silicon steel is used.

PRECAUTIONS IN PLACING AND USING INSTRUMENTS. The weight of the moving element of an electrical instrument or meter is carried by a steel pivot resting on a jewel bearing, and the area of the surfaces in contact is so minute that the pressure is very great. The operating forces are very small. Accidental shocks which would not damage a steam gage or a gas meter may blunt the pivot and destroy the usefulness of an electrical instrument. If portable instruments are to be used where vibration is unavoidably present, they should be placed on pads of folded cloth, felt, or similar material. **Do not hammer on a table or bench on which instruments are placed.** Switchboard instruments should preferably not be put in place until all work on or near the boards has been finished.

Instruments to be transported by automobile should preferably be packed in excelsior in suitable boxes. If this is not done, they should be placed on the seat cushions, upside down or on edge, in order to minimize the liability of damage to the lower pivot and its jewel. Instruments to be shipped by rail should be upside down when the packing case is right side up.

Tapping an instrument while it is being read is usually unnecessary if it is properly constructed and in good order, but when slight friction is present its effect can be eliminated by gently tapping the instrument. Hard tapping defeats its object, and may cause damage to pivots and jewels.

Portable instruments are nearly always calibrated with the scale in a horizontal plane. For the most accurate results they should be used in this position. The moving system should be mechanically well balanced so that no appreciable error will be introduced if the instrument is not exactly horizontal. New instruments should be examined for balance by tipping them about 10 deg from the horizontal, in various directions. If the zero reading varies more than a few tenths of a division during this test, the moving system is not well balanced. Tipping an instrument by too great an angle (say 45 deg or more) may give misleading results by causing the point of contact of pivot and jewel to shift, thereby changing the axis of rotation.

Avoid wiping the glass cover over the pointer of an instrument before taking readings because the resulting electrostatic charge on the glass will attract the pointer. Very large errors from this cause are possible with some types of instrument. If for any reason the cover glass has recently been rubbed, breathe on it to dispel the charge.

Wires attached to instruments should preferably extend back over the table and away from the observers. When such wires are draped over the front of the table they are sometimes accidentally caught by the observer and the instrument is thrown to the floor. If it is impossible to avoid having the wires placed in this way, they should be clamped to the table near the instrument.

Instruments should be kept at a distance from motors, generators, transformers, or cables carrying large currents, in order to avoid error caused by **stray magnetic field.** Unshielded instruments should not be placed close together; for example, a particular type of unshielded d-c instrument, widely used, will be affected by about 1 per cent by a similar instrument placed alongside it, and about 2 per cent if the instruments are in contact with their magnetic poles facing each other. This disturbance occurs regardless of whether the second instrument is in circuit.

Instruments should not be used in **extreme temperatures,** if this can be avoided. Even though no permanent injury may result, the indications of all instruments change to some extent with temperature. This effect is very small in d-c voltmeters and in moving-iron ammeters, but may be large in d-c ammeters and millivoltmeters.

In any current-carrying part of an instrument the heating increases at least as the square of the current. Great care should be used to **avoid passing excessive currents** through instruments. All set-ups should be checked over carefully before the current is turned on, to see that no instrument will be overloaded. In using **multiple-range instruments** with unknown or doubtful values of current or voltage, always begin with

the highest range. Special care is necessary in the use of **millivoltmeters**, which will usually be damaged by connection to a single dry cell. Wattmeters have three operating limits, namely, current, voltage, and power, of which only the last named is shown by the position of the pointer. The fact that the current or the voltage is excessive, in cases where the power is relatively small, can reveal itself only by smoke or other sign of thermal damage. In using a **millivoltmeter with shunts, always attach both of its leads to the shunt** before connecting the other ends to the millivoltmeter, and in disconnecting **take the leads off the millivoltmeter first.** When the reverse procedure is followed, and only one end of one of the leads remains to be connected to the shunt, an accidental contact between this end and a switch blade or other live part, or a grounded metal object, may burn out the millivoltmeter instantly.

In connecting instruments into circuit, see that all **contact surfaces** of wires, lugs, binding posts, etc., are clean and that connections are firmly made. If the test is to last for a number of hours, it is advisable to provide **switches for bypassing** the current around ammeters and the current coils of wattmeters. (Modern watthour meters are made to carry three times rated current.) The switches are to be opened when readings are to be taken. Switches may be provided also to disconnect a-c voltmeters and the voltage circuits of wattmeters, if these instruments do not have keys. The power required by d-c voltmeters is so small that this precaution is unnecessary for them.

If an ammeter must be connected directly in a line, it is advisable to put it in the **grounded wire**, if available, to protect the operator and the instrument.

If an instrument has been dropped, overloaded, or exposed to abnormal temperatures, it should be checked, say by comparing it with a similar instrument not so exposed, before continuing to rely on its indications.

A heavy short circuit in nearby conductors, even though of extremely short duration, is likely to partially demagnetize the magnet of a d-c instrument. After such an exposure the instrument should be rechecked, even though it has sustained no visible injury.

Repairs to instruments, if at all extensive, are usually best made at the factory. Electrical instruments are so delicate that repairs elsewhere should not be attempted unless equipment and some experience are available. Instruments should be opened only in a clean dry place free from lint, dust, metal filings, etc. Direct-current instruments have very strong permanent magnets and very small clearances for the moving coil, and should never be opened on a workbench where iron filings may be present.

Small displacements (say a few tenths of a division) of the pointer from the zero mark, when no current is flowing through the instrument, may be corrected by turning the zero adjuster. Large displacements (several divisions) may indicate bending of the pointer or other derangement, and the consequent need for repairs. The use of the zero corrector to bring a bent pointer back to zero usually introduces appreciable errors.

The heads of binding posts should be screwed down before instruments are put away. Instruments are sometimes picked up by the binding posts, and this always unsafe procedure reaches a maximum of insecurity when the binding-post heads happen to be loose.

DETAILS OF DESIGN AND STRUCTURE OF ELECTRICAL INSTRUMENTS. Space limitations permit only references to sources of information on the numerical design of the windings, springs, magnets, damping mechanisms, etc., of electrical instruments. The more important ones are Drysdale and Jolley's books on Electrical Measuring Instruments, Edgcumbe and Ockenden's book on Industrial Electrical Measuring Instruments, Keinath's book, Die Technik der elektrischen Messgeräte, and the technical journal *Archiv für technisches Messen*. The *Journal of Scientific Instruments* (London) publishes, from time to time, numerical data on the construction and functioning of electrical measuring instruments.

12. ELECTRICAL INTEGRATING METERS

Amperehour Meters

Amperehour or quantity (coulomb) meters may be classified as electrolytic meters and motor meters. They are used in this country chiefly for storage-battery work. Amperehour meters of small current rating are used abroad as substitutes for watthour meters, and are calibrated to read directly in kilowatthours at some assumed voltage.

ELECTROLYTIC AMPEREHOUR METERS. This type of meter is used extensively in Europe, but is rarely (if ever) used in this country. The meter generally consists of a glass vessel or U-tube containing an electrolyte, such as water, or an aqueous solution of a salt of mercury or of caustic soda. The solution is decomposed by the current, and since the rate of decomposition is proportional to the current, the deposit of metal or the quantity of gas evolved can be used to measure the electrical quantity

in amperehours. In some types the entire current to be measured is passed through the electrolyte, and in others the bulk of the main current passes through a shunt and only a very small part through the electrolyte.

MOTOR AMPEREHOUR METERS. The essential parts of the motor amperehour meter are the motor element, the brake or speed-regulating device, and the register. The motor consists of an armature rotating in the field of a permanent magnet. Usually only a shunted portion of the current flows through the armature. Motor amperehour meters are intended to be cheaper and if possible more rugged than the ordinary watthour meter. The absence of a constantly excited voltage circuit in the meter avoids the constant loss of energy in such a circuit.

COMMUTATOR AMPEREHOUR METER. The commutator amperehour meter in its simplest form usually consists of one or two permanent magnets which provide a driving field within which rotates an armature with three coils and a three-part commutator. In some designs the armature coils are mounted flat on an aluminum disk which in addition to supporting the coils produces the retarding action in connection with the field magnet. In another design there is a stationary iron core between the poles of the field magnet and a drum armature rotating in the gap between this iron core and the pole faces of the field magnet. No braking device is used in this latter type, and the motor runs at a speed proportional to the impressed emf, taking only sufficient power to overcome the friction in the bearings and in the gear train.

Amperehour meters of the commutator type are gradually passing out of use because of their inferior accuracy at light loads and the difficulty of adequately insulating the windings from the framework of the meter.

MERCURY-MOTOR AMPEREHOUR METER. In the mercury-motor amperehour meter, current is carried to the armature by mercury, which takes the place of the brushes and commutator of the ordinary d-c motor. One form consists of a copper disk armature mounted in jeweled bearings and immersed in mercury. The current is led into and out of the mercury chamber through suitable terminals, and since mercury has about 55 times the resistivity of copper, the greater part of the current goes diametrically across the disk. A device used to compensate for the increase of fluid friction with increase of speed takes some such form as an auxiliary coil, in series with the motor element, which produces a flux which augments the flux cutting the driving disk.

SPECIAL FEATURES OF AMPEREHOUR METERS. Amperehour meters used for showing the state of charge of storage batteries are sometimes provided with special features. For example, a "compensation for overcharge" causes the meter to run more slowly on a given value of charging current than on the same value of current during discharge. The percentage difference in the two cases is chosen to provide for the excess that must be put into the battery because it is not 100 per cent efficient. This is accomplished by a "variable resistor element" in parallel with the main mercury chamber. A pivoted copper bar in this element is immersed in mercury, and is cut by some of the flux from the driving magnets. It will thus change its position with the reversal of current direction, and will vary the resistance of the element. The "compensation for light-load accuracy and internal battery losses" consists of a thermocouple heated by a potential winding and delivering a small current continually to the motor element in the direction corresponding to battery discharge. This action may be adjusted to cause the meter to record the loss of charge when the battery is not in use. The "thermal shunt method" of compensation for high discharge rates consists in making the shunt to the motor element of iron or other material of high temperature coefficient, and so designing it that it will heat up at the heavier loads. This causes the amperehour meter to have a higher percentage registration as the load increases.

Amperehour meters are sometimes provided with contacts which actuate auxiliary devices, such as circuit breakers, bells, or other signaling devices. This feature is used in connection with battery charging and electroplating.

Watthour Meters

GENERAL. A watthour meter consists essentially of (1) a small electric motor, which may be either of the commutator type, mercury and disk type, or induction type; (2) a brake system composed of a disk of non-magnetic conducting material (usually aluminum) mounted on a spindle and arranged to rotate between the poles of one or more permanent magnets; and (3) a register indicating a number proportional to the number of revolutions of the disk. One winding, called the voltage coil, is connected in shunt with the load; and the other winding, called the current coil, is connected in series with the load, the connections being the same as for an indicating wattmeter. These connections may be made either directly or through suitable instrument transformers.

PRINCIPLE OF OPERATION OF WATTHOUR METERS. Watthour meters are so constructed that the average torque exerted by the motor is proportional to the average power in the load. The brake system is so designed that the opposing torque, due to the eddy currents induced in the disk, is proportional to the speed. When the speed is steady the driving torque must be equal to the opposing torque, and therefore proportional to the speed. Hence the speed of the disk is proportional to the average power in the load, and the total number of revolutions which the disk makes during any interval must be proportional to the total energy which has passed through the meter during this interval, whether the power remains constant or varies. To determine the energy input to the load in watthours or kilowatthours during a given interval it is therefore only necessary to take the difference between the dial readings at the beginning and end of the interval, and to multiply by the proper constant if the meter is not direct reading.

SOURCES OF ERROR IN WATTHOUR METERS. In a d-c watthour meter the chief sources of error are the somewhat variable friction of the brushes, friction of the bearings and register, and air friction. In a-c watthour meters, the lack of exact 90-deg phase relation between the impressed voltage and the magnetic flux due to the current in the voltage coil may cause additional errors which vary with the frequency and power factor and also with the distortion of the wave form; in well-designed modern meters these errors are practically negligible. Instrument transformers introduce additional sources of error which may be undesirably large if the transformers are not properly designed or if the burden is excessive.

COMMUTATOR TYPE OF WATTHOUR METER. The commutator type of meter, used only on d-c circuits, consists of a set of stationary field coils which carry the load current, and an armature wound with fine wire which is connected in shunt with the supply circuit. A resistor is usually connected in series with the armature, and the ir drop in it and in the armature itself is almost exactly equal to the line voltage at any practicable speed of revolution. In other words, the counter emf of the armature is too small to have any appreciable effect on the speed, which explains why an increase in the current in the fixed (field) windings increases the speed instead of reducing it as in ordinary shunt motors. The connection to the armature is by a commutator and brushes, as in an ordinary d-c commutator motor. Special designs are sometimes adopted for very large capacities, such as double armatures astatically arranged, and damping magnets inclosed in a laminated iron shield in order to reduce stray-field errors where heavy currents are used and heavy short circuits may occur. A four-pole construction with a single armature is also used for the same purpose.

Compensation of Commutator-type Watthour Meters for Friction. Friction in a well-designed d-c watthour meter should have a noticeable effect only on light loads. To compensate for it, a "light-load adjusting coil" is added, which is an auxiliary or compounding coil connected in series with the armature. It is placed adjacent to the field coils so that its field strengthens the main field and produces a slight torque independent of the load and just sufficient to compensate for friction.

Details of Construction, Bearings, etc. The design of the modern d-c commutator watthour meter includes close electromagnetic coupling between the armature and field coils, a light-weight armature, a commutator of very small diameter, and brushes having very small friction but able to stand the wear and carry the current without undue sparking and pitting of the contact parts. The lower bearing, which carries all the weight, usually consists of a steel pivot supported by a cupped and polished jewel, usually of sapphire. In some meters, particularly in high-capacity ones with astatic armatures and a correspondingly heavy weight, diamond jewels are used.

Current Ratings of Commutator Watthour Meters. Commutator-type d-c meters are built with current ratings ranging from 5 to 10,000 amp, 100 to 600 volts. Meters of this type are furnished with double current circuits for three-wire service, the maximum ampere capacity for three-wire meters being about 6000 amp. Special meters have been supplied for 1200- and 2400-volt railway circuits.

Accuracy of Commutator-type D-c Watthour Meters. Tests on d-c commutator meters show that a meter of good design should start on 2 per cent of full load and should give accuracies about as follows: to within $3^1/_2$ per cent from 5 per cent to $^1/_4$ load, 2 per cent from $^1/_4$ to full load. The Code for Electricity Meters (see Bibliography) requires d-c watthour meters to run continuously on normal voltage and 2 per cent of rated current, and for higher loads to be accurate within the following limits:

Per cent rated current.........	5	10	20	50	100	150
Maximum deviation, per cent...	6.0	3.0	2.0	2.0	2.0	2.0

For a summary of the meter accuracies required by commission regulations, city

ordinances, and state statutes, see Bureau of Standards Circular 56, Standards for Electric Service.

MERCURY-MOTOR WATTHOUR METER. The mercury-motor d-c watthour meter has a copper disk armature submerged in mercury. The line current enters and leaves the mercury through two electrodes diametrically apart. Since mercury has about 55 times the resistivity of copper, the major part of the current traverses the disk. A laminated iron electromagnet having many turns of fine wire is connected across the line, and sends through the copper disk a magnetic flux proportional to the line voltage. A shaft attached to the disk passes through tubes constructed to prevent the mercury from escaping when the meter is inverted. Externally, this shaft carries a worm which engages with the register train, and an aluminum damping disk moving in the field of a permanent magnet. The submerged copper disk carries a float so proportioned that there is a slight upward thrust. In consequence, the lower bearing is a ring-stone jewel, while the upper end of the shaft is carried in a ring-stone end-stone bearing. The driving torque is proportional to the power supplied to the load. The damping at small and moderate loads is nearly all caused by the drag disk, but at full load and overloads the fluid friction of the mercury increases at a rate which would cause a drop in the accuracy curve unless compensated. Compensation is effected by passing the line current through a few turns of heavy wire around the voltage electromagnet. The copper disk is slotted radially to reduce the damping effect which would be caused by the flux from the voltage electromagnet. This expedient reduces the influence of variation of voltage on the accuracy of the meter.

Compensation of Mercury-motor Watthour Meter for Friction. The compensation for friction is effected by a thermocouple shunted around the mercury chamber and heated from a resistance coil connected in series with the voltage circuit. The small emf generated in the thermocouple sends a current through the armature which is sufficient to overcome the friction of the moving parts.

Application of Mercury-motor Watthour Meters. On account of the low resistance of the current circuit, mercury-motor watthour meters are particularly well adapted for use with external shunts, and are used for switchboard work where large currents must be metered. They withstand vibration and shocks better than commutator meters.

Current Ratings of Mercury-motor Watthour Meters. Direct-current mercury-motor watthour meters have a full-load current rating of 10 amp. For all higher ranges external shunts are used. Shunts with ratings up to 60,000 amp have been furnished. Meters designed for voltages up to 700 volts are regularly furnished and special meters have been supplied for 1200- to 3000-volt d-c railway circuits.

Accuracy of Mercury-motor Watthour Meters. The load-accuracy curve at normal voltage is said to deviate from a straight line by less than 0.5 per cent from 5 per cent to 200 per cent of rated load.

INDUCTION WATTHOUR METER. The essential elements of a typical induction watthour meter are shown in Fig. 33. A laminated electromagnet has three cores carrying a voltage coil and two current coils. The voltage coil, of many turns of fine wire, is connected across the line; the current coils, of a few turns of heavy wire, carry the load current. The magnetic flux set up by the voltage coil would be in quadrature with the applied voltage but for the iron loss and copper loss in the voltage electromagnet. Exact quadrature is obtained by expedients of which that shown in Fig. 33 is typical, namely, the use of a so-called lag coil closed through an external resistance (not shown). This resistance is adjusted by trial to give the quadrature relation at rated frequency. In some designs a metal plate forming a closed loop is used instead of a wound lag coil. The flux of the current electromagnet is practically in phase with the load current.

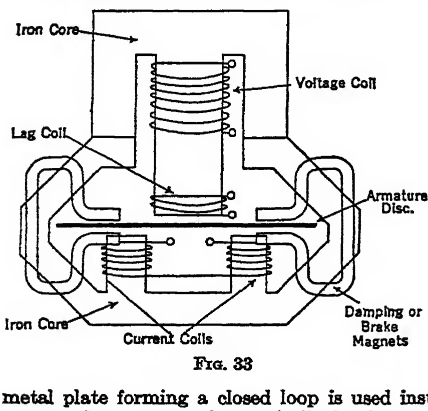

FIG. 33

Principle of Operation of Induction Watthour Meter. Currents induced in the disk flow about each pole in the general form of concentric circles. The driving torque results from the interaction of each induced current with the flux which does not induce it. When the load power factor is unity, each induced current will be in phase with the flux

with which it reacts to produce torque, and as the power factor of the load becomes less than unity, this torque will decrease in proportion to the cosine of the angle of lag (or lead) in the load. Hence the driving torque is proportional to the power in watts taken by the load. The retarding torque of the damping magnets is proportional to the speed of rotation, and the speed will therefore be proportional to the power taken by the load. The total number of revolutions over any given period will be proportional to the energy in watthours.

Compensation of Induction Watthour Meter for Friction. To maintain accuracy down to very light loads, the friction of the bearings and of the register is usually compensated by placing a metal plate, forming a closed loop, near the pole of the voltage electromagnet with means for adjusting it in a plane at right angles to the axis of the voltage coil. The current induced in this loop produces a flux out of phase with the flux of the voltage coil, and the interaction between each of these two fluxes and the current induced in the disk by the other produces a slight turning moment, independent of the load current, which is adjusted by shifting the light-load plate until the frictional moment is just balanced.

Recent Improvements in Induction Watthour Meters. Cooperating with the meter committees of the electric power industry American manufacturers have steadily improved their meters. Notable improvements made in recent years include (1) compensation for temperature changes, (2) extension of the range of accurate registration up to 300 per cent of rated load. Compensation for temperature, for loads of unity power factor, is obtained by locating pieces of magnetically temperature-sensitive alloy near the retarding magnets so as to bypass some of their flux. The permeability of these alloys changes appreciably with room temperature, and by proper design the effective braking flux may be made to change with temperature by the right amount to keep the accuracy of the meter unchanged with loads of unity power factor. The change of resistance of the voltage coil with changing temperature causes a small shift in the phase of its flux with respect to the line voltage, and in consequence, a change in the accuracy of the meter on loads of low power factor. Compensation for this effect of temperature change is obtained, to a greater or less extent, by various expedients which affect the flux of the voltage electromagnet.

Multi-element Induction Watthour Meters. Polyphase induction meters are usually made by combining two (or three) single-phase meter elements with their disks mounted on a common shaft. Two-element meters are used for 3-wire 3-phase circuits, and also for metering 3-wire single-phase loads with an accuracy which is independent of current and voltage unbalance. Three-element meters are used to meter 3-phase 4-wire loads. Although it is possible to meter 3-phase 4-wire loads with a special 2-element meter equipped with a third current circuit divided between the two current electromagnets, such meters are subject to errors from unbalance of the voltages.

Accuracy of Induction Watthour Meters. For the induction meters now in American production the makers' stated accuracy is 0.5 per cent or better from "light load" of, say, 5 per cent of rated watts up to 300 per cent of rating. Such a performance is needed for residence meters because electrically operated household appliances are widely used. Meters of the older designs of larger current rating, say 15 amp, would not correctly register on very light loads.

Current transformers do not have a large continuous overload capacity; for example, a secondary current of 7.5 amp would probably be considered an upper limit for a secondary rating of 5 amp. The use of a modern 5-amp watthour meter with a current transformer is inefficient, and meters rated at 2.5 amp are coming into use for this purpose.

Performance Data of Induction Watthour Meters. For the single-phase watthour meters now in production (1936) the following representative data are given by the manufacturers: weight of moving element, 13 to 16 grams; torque at rated load in watts, 40 to 53 millimeter-grams; rpm at rated load in watts, 28.75 in 3 makes, 16 in the fourth. Loss in voltage coil at rated voltage, 0.9 to 1.4 watts; loss in current coil at rated current, for 5-amp meters, 0.15 to 0.30 watt.

Standardization of Induction Watthour Meters. Within recent years, two important steps toward uniformity have been taken by the four American makers. The direction of rotation of the disk has been made the same in all induction meters now in production, namely, counter-clockwise as seen from above the disk. Three of the four makers have adopted a uniform value of disk constant, namely, $1/3$ watthour per disk revolution for a 5-amp 115-volt 2-wire meter. The fourth maker has adopted a disk constant of 0.6. Studless glass covers are being used by all makers. The greater overload capacity, with sustained accuracy, permits a reduction in the number of ampere ratings used. The so-called "new sequence" (meter, switch, fuse) now permissible in customers' installations is stimulating the development of meters and weatherproof cases for outdoor use. Outdoor

meter installations save the time of meter readers and testers, and tend to discourage the theft of current.

MAINTENANCE AND TESTING OF WATTHOUR METERS. The use of a portable standard watthour meter ("portable test meter" or "rotating standard") is the accepted method not only for checking customers' meters in position but also for testing repaired or exchanged meters in the meter laboratory. These standard meters should be checked against an indicating wattmeter and a time standard, at intervals depending upon the conditions of use. To facilitate the testing of customers' meters, a large number of artificial-load and other devices are available. For details, consult the Handbook for Electrical Metermen (see Bibliography). Additional valuable information on devices and methods for watthour meter testing and on demand meters, indicating instruments, potentiometers, etc., is contained in the subsequent Reports of the N.E.L.A. Meter Committee under the heading of New Developments.

Demand Meters

The charge to any customer should logically be made up of a part fixed by the maximum power in kilowatts taken at any time during a certain definite period, and another part fixed by the total energy used during the same period. The demand system of charging tends to improve the load factor of the station and to distribute its fixed charges more equitably among its customers.

A large number of variables are involved in the problem of demand metering, including the rating of generators, lines, and transformers, and the diversity factor, load factor, and power factor of the system. No practical meter has yet been devised to take into account all these variables; consequently, charges based on the use of demand meters in addition to the usual energy meters must necessarily be somewhat arbitrary.

REQUIREMENTS OF A DEMAND METER. The energy supplied to the customer is measured by a watthour meter; the maximum power (in kilowatts) taken by him is measured by some form of demand meter. For d-c supply at practically constant voltage a device which measures the maximum current is as satisfactory as one which measures maximum power, but when the voltage or power factor (in case of an a-c system) varies, the maximum-current indicator is not suitable. In any case, the demand meter should not measure the instantaneous peak but rather the average of the power demanded by the customer over a specified time interval, for the maximum demand recorded should not be unduly influenced by short circuits, excessive starting current of motors, or any other abnormal demand over a time too short to have any real effect on the generator and line capacity which must be provided. This time interval should theoretically differ with the character of the installation and the relation of its maximum power demand to the maximum station capacity. In relatively large customers' installations the time should be carefully chosen with reference to the time that the central station can endure an overload successfully. Hydroelectric plants have a very definite power limit which is reached with maximum gate opening, while steam-power plants have considerable thermal inertia and their boilers and generating apparatus can usually carry relatively large overloads for a considerable time. These considerations require much shorter time intervals for large users of hydroelectric power than would be necessary in steam plants of corresponding magnitude.

Demand intervals of 15 minutes, 30 minutes, and 1 hour are those in general use at the present time. For very special installations, intervals as short as 1 minute and as long as 3 hours have been used. The general tendency is toward the use of a single interval for a given system, and toward the use of intervals larger than those formerly employed.

To improve the load factor, the off-peak system of rate schedules has been developed, which gives a preferential rate to customers utilizing current during the times of light load. Demand meters giving time of day as well as demand are used for this class of metering.

CLASSIFICATION OF DEMAND METERS. Demand meters may be classified into (1) **curve-drawing instruments,** giving the load-time curve of the installation; (2) **integrated-demand meters** consisting of an integrating meter combined with a device which registers the energy consumption from time to time in such a way as to indicate or record the maximum demand; (3) **lagged-demand meters,** which require a certain time interval for the indication to reach the value corresponding to the load. Under each of these types there are a number of further distinctions, such as length of demand interval, whether the demand intervals begin at specified times of the day or may be so chosen as to include the maximum average load during any time interval of the given length, and whether the maximum demand is simply indicated without reference to time or is recorded so that the time of its occurrence may be determined.

CURVE-DRAWING INSTRUMENTS AS DEMAND METERS. The most complete knowledge of the conditions attending the customer's use of energy may theoretically be obtained by using a curve-drawing wattmeter, with which the average demand for any time interval may be found and also the time at which it occurred. In practice, however, unless the paper speed is fairly high, the lines will run together so as to make it difficult or impossible to determine the demand with any approach to accuracy. Curve-drawing wattmeters are expensive, and their indications are difficult of comprehension for the ordinary customer. They are used largely by central stations to accumulate demand data. Curve-drawing ammeters may be used on the assumption of constant voltage and power factor, but they do not give as accurate information as wattmeters.

INTEGRATED-DEMAND METERS INDICATING MAXIMUM DEMAND ONLY. The Types M-16 and M-19 demand meters of the General Electric Co. and the Type G demand meter of the Sangamo Electric Co. consist essentially of a demand-registering and a timing mechanism mechanically connected and mounted within the same case. The demand-registering element is electrically operated by means of a contact actuated by the watthour meter in conjunction with which the demand meter is used. The registering element consists of a train of gears which drive a demand pointer forward over a dial. This train is actuated by a ratchet-and-pawl mechanism operated by an electromagnet which receives an impulse every time a certain amount of energy is registered by the watthour meter. The speed of advance of this pointer is therefore proportional to the power. The pointer-driving mechanism is reset to zero position at the end of each time interval, leaving the pointer itself in the highest position reached. This resetting is accomplished by a mechanism controlled either by a clock or by a constant-speed motor. These demand meters are for use on a-c circuits, and are arranged for intervals of 15, 30, or 60 minutes. The Type M-16 demand meter, for a-c service, is timed by a Warren synchronous motor; the G.E. Type M-19, and the Sangamo Type G, for d-c service, have a motor-wound spring-driven clock. The Type M-14 demand register, when used in appropriate General Electric a-c watthour meters instead of the regular register, serves the same purpose as the M-16 and M-19 demand meters and also has the usual four dials showing the energy registration in kilowatthours. The Westinghouse demand attachment, the Sangamo Type HB maximum demand register, and the Duncan T-1 demand register, when installed in the corresponding watthour meters in place of the usual registers, operate in the same general way and serve the same purposes as the General Electric Type M-14 demand register.

The General Electric Type I-16 MW, Type D-14 MW, and Type D-15 MW watthour demand meters perform the same functions as the I-16, D-14, and D-15 watthour meters equipped with a demand register as outlined in the preceding paragraph, but have a regular kilowatthour register and a separate demand registering mechanism. The timing element is a Warren synchronous motor.

INTEGRATED-DEMAND METERS WITH ARBITRARY TIME INTERVAL, RECORDING ALL DEMANDS AND TIME OF OCCURRENCE. The earliest instrument of this class was the printometer, later made by the General Electric Co. as the Type P demand meter. This instrument printed on a paper tape at regular time intervals the time of record and the energy consumption registered up to that time by a watthour meter. Cyclometer type-wheels were moved forward, at a rate proportional to the power, by means of a solenoid, the energizing circuit of which was closed through a contact wheel fixed to one of the spindles of the gear train of the watthour meter. The reading of the cyclometer was printed on a paper tape by a copying ribbon and a rubber platen actuated by a solenoid which was energized at regular time intervals by means of a contact-making clock. The time was also printed opposite each cyclometer reading. Thus, the difference between consecutive recorded values on the tape was proportional to the energy consumption in kilowatthours in the circuit during a definite time interval. The average demand in kilowatts over a period of time, corresponding to the interval between successive operations of the printing solenoid, was obtained by dividing the kilowatthours of energy consumption during a time interval by the length of the interval in hours.

The Type PD demand meter is based on the same general principles as the Type P demand meter just described, but contains new features which reduce the labor of discovering the maximum demand. The printing wheels automatically return to zero at the end of each time interval, hence each printed record shows the demand during the interval just elapsed. This eliminates the necessity of subtracting readings in order to obtain the demand. The PD demand meter also has three dials giving, respectively: an indication of the maximum demand since the meter was last reset; a reading of the demand at any instant; and the total number of contact impulses delivered to the demand meter, which may be used in checking the total registration of the demand meter with that of the watthour meter.

The Type RA recording-demand watthour meter of the Westinghouse Co. consists of a polyphase watthour meter combined with a mechanism for obtaining a permanent graphic record of the integrated demand in kilowatts over successive predetermined time intervals. The total energy consumption is shown in the usual way by the register of the watthour meter. The time interval is controlled either by a hand-wound 35-day clock or by a synchronous-motor clock. A separate spring mechanism advances the record paper. The pen is moved across the paper by the gear train of the watthour meter, and at the end of each time interval a release mechanism frees it from the gear train and allows a weight to move it back to zero where it is again meshed with the gear train to repeat its advance during the next time interval. Just before the release occurs, the record paper is advanced slightly so that the pen makes a distinct record of the maximum travel, which is a measure of the integrated demand. The time of occurrence is shown by the time figures printed on the paper. This meter is made with time intervals of 5, 15, 30, or 60 minutes. It is a self-contained structure, with the metering and demand-recording mechanisms mechanically connected.

The Westinghouse Type RB recording-demand watthour meter is a development from the Type RA and functions in the same general manner. It employs OB watthour-meter elements and has a synchronous motor which drives the timing device and the chart-driving mechanism.

The General Electric Type G-9 demand meter is used in connection with a watthour meter, and gives a graphic record on a circular chart of the demands integrated over definite time intervals, with the time of day and day of week of their occurrence. It consists essentially of a registering element and a timing element. The registering element is electrically connected to the watthour meter, which has a contact device either on one of the spindles of the register or in a separate mechanism operated by the rotating element. This contact device alternately makes and breaks the circuit of a solenoid in the registering element each time a definite amount of energy is registered by the watthour meter. An armature operates a ratchet-and-pawl mechanism to advance the stylus by a small step for each operation of the contacts. At the end of each time interval a cam mechanism operated by the timing device allows the stylus to return to the zero position, where it is re-engaged ready to integrate the energy used in the following interval. The timing mechanism rotates the chart continuously, giving a record in the form of a saw-tooth polar curve. The chart gives a record for one week or one month. The time interval is either 15, 30, or 60 minutes.

The General Electric Type GM-10 demand meter is a development from the G-9 demand meter, and is for the purpose of assisting the plant operator to keep the maximum demand at the lowest practicable level. Alarm contacts used for this purpose in previous demand meters had the serious limitation that they closed after the predetermined maximum demand had been reached. The GM-10 demand meter avoids this limitation by having the alarm contacts so arranged that they will close if for any part of the time interval the integrated load (number of impulses transmitted by the watthour meter to the demand meter) has exceeded a predetermined and adjustable value for the elapsed part of the time interval. To accomplish this, a so-called "ideal-demand" mechanism has been added to the G-9 demand meter. Type GM-10 demand meters are made for use on a-c circuits only, and employ the Warren clock motor as the timing element.

The Type DG-1 watthour demand meter of the General Electric Co. is a combination of a two-element polyphase watthour meter and a block-interval demand meter which records the demand for each definite time interval on a strip chart. The watthour-meter disk shaft has the usual worm at the top which drives the register and a second worm at the bottom which drives the recording pen mechanism through a gear train and clutch. The timing is accomplished by a Warren motor which also drives and rerolls the chart, winds a resetting spring, and actuates the resetting mechanism. Standard time intervals are 15, 30, and 60 minutes.

THERMAL-STORAGE LAGGED-DEMAND METERS. These meters all show maximum demand only, and the indication depends on the duration of the load as related to the demand interval of the meter, as well as on the previous history of the load. The demand interval of this type of meter is usually taken as the time required for the indication to reach 90 per cent of the full value of a steady load which is thrown suddenly on it.

The Type H-2 demand meter of the General Electric Co. is an ampere-demand instrument based on the differential thermometer principle, using a pair of strips of thermostatic metal. One of these is in proximity to a heating element traversed by the load current, while the other nominally follows the room temperature. For a given change in temperature the two strips tend to move in opposite directions, and with no current flowing through the heating device the pointer remains at zero. Current flowing through the

heating device heats the adjoining strip and moves the pointer over the scale. The pointer remains at the highest point reached until manually reset.

The Lincoln Type A.D. demand meter indicates maximum ampere demand on either d-c or a-c circuits. In the two-wire Type A.D. meter a shaft carries the demand pointer and two bimetallic spiral coils which tend to rotate the shaft in opposite directions when their temperature is increased. A heater carrying the line current (or a definite part of it, when shunts or current transformers are used for the larger capacities) is arranged so as to heat only one of the spirals. The angular deflection of the pointer, when a steady state is reached, is proportional to the square of the current, but the scale is marked either in terms of the first power of the current or in kilowatts for an assumed value of line voltage. The three-wire Type A.D. demand meter operates in a similar manner but has three heating coils, two of equal resistance being connected in the outside wires and acting on one bimetallic spiral while the third heater, having one-half the resistance of each of the others, is connected in the neutral wire and acts on the second spiral. This arrangement ensures that the maximum ampere demand of the three-wire circuit will be correctly measured, regardless of the degree of unbalance of the load.

The Lincoln Type W. D. demand meter is constructed on the principle of the hot-wire wattmeter and indicates demand in kilowatts. In construction it resembles the two-wire Lincoln Type A.D. meter just described, but differs in that two heaters are used, one acting on each of the two bimetallic spirals. The meter contains a small transformer supplying a low-voltage current to the two heating coils connected in series. The line current is brought in at the central point on the secondary winding of the transformer and flows through the two heating coils in parallel and on to the load. One heating coil therefore carries one-half the line current plus a current proportional to the line voltage, and the other heating coil carries one-half the line current minus the current which is proportional to the line voltage. It may be shown that the resulting difference in rate of heat liberation in the heaters, and therefore the angular deflection of the pointer, will be proportional to the load in kilowatts, for any power factor. The Type W.D. meter is internally shunted in the larger capacities.

DEMAND METERS TAKING ACCOUNT OF POWER FACTOR. The increasing appreciation of the effect of low power factor on the cost of energy supply has resulted in the development of demand devices taking power factor into account. The Westinghouse Type RI kva recording demand meter resembles the Type RA recording demand meter described above but has also a second polyphase meter which is connected by means of phasing transformers to register the kilovarhours (reactive kilovolt-ampere hours). This meter and the energy meter drive two small aluminum disks on which rests an aluminum ball. A third disk, in contact with the ball, is caused to rotate at a speed which is equal to the vector sum of the speeds of the other two disks. The total kilowatthours and total kilovarhours are shown by the usual registers on the energy meter and the reactive-component meter. The graphic record shows the kilowatt demand and the kilovolt-ampere demand during the predetermined time interval, from which the average power factor during any time interval may be found.

The Sangamo Type S kva demand meter is controlled by two watthour meters which measure the energy in kilowatthours and the reactive component (kilovarhours), respectively. It gives a record on a single chart from which the following information about the load can be obtained: (1) the kw demand; (2) the kva demand; (3) the maximum kw demand; (4) the power factor at time of demand; (5) the reactive-component demand; (6) the time of occurrence of the demand; (7) the energy component in kilowatthours; (8) the reactive component in kilovarhours (reactive kilovolt-ampere hours). The power triangle for any given demand interval is drawn on a strip chart. The energy is measured by a watthour meter, and the registration is transferred by electrical means to move a stylus horizontally across a vertical paper chart which is driven (by electrical means) by a second watthour meter connected so that it integrates the reactive component. Both the kilowatthours and the kilovarhours are shown by registers in the kva meter. A pusher arm mechanically connected to the energy stylus advances a friction pointer which shows the maximums kw demand. A small synchronous motor drives an auxiliary stylus across 13 equally spaced time (hour) divisions at the right of the chart, and also trips the energy stylus and returns it to zero at the end of each predetermined time interval.

13. INSTRUMENT TRANSFORMERS

APPLICATIONS. An instrument transformer is a transformer in which the conditions of current or voltage and of phase position in the primary circuit are represented with acceptable accuracy in the secondary circuit. An instrument transformer may be

either an instrument current transformer or an instrument potential (voltage) transformer. These terms are usually abbreviated to current transformer and potential (voltage) transformer, respectively. Both kinds of transformer are applicable for measurement and control purposes. The current transformer is intended to have its primary winding connected in series with the circuit carrying the current to be measured or controlled, and the voltage transformer is intended to be connected in parallel with the circuit.

The use of instrument transformers separates the secondary measurement and control devices from the dangerous line voltage and also permits all these devices to have a single rated current and a single rated voltage. For measurement purposes high accuracy is important; for the operation of control and protective devices a very moderate accuracy is sufficient but reliability and ruggedness are of the highest importance. It is therefore frequently advisable to use separate transformers for the two functions, even at an increased cost.

DEFINITIONS. The **true ratio** of a current transformer or a voltage transformer is the ratio of the rms primary current or voltage, as the case may be, to the rms secondary current or voltage, under specified conditions. The quotient obtained by dividing the true ratio by the nominal ratio (as marked on the name plate) is often called the "ratio factor" or "ratio correction factor."

The **phase angle** of a current transformer or a voltage transformer is the angle between the primary current or voltage vector and the secondary current or voltage vector reversed. This angle, by international agreement, is considered as positive when the reversed secondary current or voltage vector leads the primary current or voltage vector. The phase angle of a current transformer is often denoted by the letter β, that of a voltage transformer by γ. The phase angles β and γ may be inherently either positive or negative, depending on the characteristics of the particular transformer and its burden.

If a wattmeter is connected to the secondary circuits of a voltage transformer of ratio R_v and phase angle γ, and of a current transformer of ratio R_c and phase angle β, the true power P in the primary circuit is given by

$$P = P_s R_v R_c \frac{\cos(\theta_2 + \alpha + \beta - \gamma)}{\cos \theta_2} \tag{12}$$

where P_s is the power indicated by the wattmeter; θ_2 is the apparent phase displacement by which the voltage leads the current as deduced from the indications of the instruments in the secondary circuits; and α is the phase angle of the voltage circuit of the wattmeter. Tables of values of the correction factor $\frac{\cos(\theta_2 + \alpha + \beta - \gamma)}{\cos \theta_2}$ are given in the section on Wattmeters. The correction factor for energy measurements, when a watthour meter is used with instrument transformers, is the same as that given above for power measurements.

The **burden** of an instrument transformer is that property of the circuit connected to its secondary winding which determines the flow of active power and reactive power from the transformer. It is expressed either as total ohms impedance, together with the effective resistance and reactance components of the impedance, or as the total volt-amperes and power factor of the secondary devices and connecting leads. The values expressing the burden apply conventionally to the condition of rated secondary current or voltage of the instrument transformer and a stated frequency, both of which must be included with the burden expression. The impedance expression is the more convenient for current transformers, the volt-ampere power-factor expression for voltage transformers.

POLARITY MARKINGS. The primary terminals and secondary terminals of instrument transformers should be so marked that, when a lead is connected to a marked secondary terminal, the polarity will be the same as if the primary conductor running to the marked primary terminal were detached from the transformer and connected directly to the lead; that is, the relation of the marked terminals is such that if the instantaneous direction of the current in the marked primary lead is toward the transformer, the instantaneous direction of current in the marked secondary lead is away from the transformer, or vice versa.

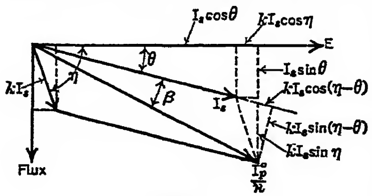

FIG. 34

RATIO AND PHASE ANGLE OF CURRENT TRANSFORMER. Refer to Fig. 34 and let

n = ratio of the number of secondary to the number of primary turns.

I_p = primary current (reversed).

I_s = secondary current.
k = ratio of exciting current (referred to secondary) to the secondary current.
η = phase angle between the exciting current and primary induced emf.
θ = phase angle between the secondary current and secondary induced emf (positive for lagging current).
β = the "phase angle" of the transformer, i.e., the angle between the primary current and the secondary current reversed.

Then the ratio of transformation is

$$\frac{I_p}{I_s} = n\left[(\cos\theta + k\cos\eta)^2 + (\sin\theta + k\sin\eta)^2\right]^{1/2}$$
$$= n\,[1 + k\cos(\eta - \theta)\ldots]\ \text{approx.} \tag{13}$$

and the phase angle is

$$\beta = \tan^{-1}\frac{k\sin(\eta-\theta)}{1 + k\cos(\eta-\theta)} \tag{14}$$

The value of the ratio k for a given primary current depends upon the impedance of the burden connected to the secondary; the higher this impedance the greater the value of k, and therefore increasing the secondary burden tends to increase the difference between the ratio of turns and the true ratio of the primary and secondary currents; increasing the secondary burden also tends to increase the phase angle β of the transformer. The true ratio I_p/I_s and the phase angle β also depend upon the power factor of the burden. The core flux required for a given induced voltage is inversely proportional to the frequency; consequently the exciting current and hence the phase angle and the departure of the true ratio from the ratio of turns will also vary approximately in inverse proportion to the frequency.

In order to use these formulas for numerical results it is necessary to know the amount and power factor of the exciting current under the particular conditions of burden. Since this is difficult to predetermine, it is customary to use curves similar to those given in Fig. 37 below, obtained by plotting actual test results.

SPECIAL DESIGNS OF CURRENT TRANSFORMERS. Although the design of current transformers is necessarily based on the same fundamental principles as that of power transformers, the conditions under which they operate (nearly short-circuited secondary and varying terminal voltage) are so special that the resulting design is very different. The flux density under normal conditions is very low (a few hundred gausses). The ampere-turns at rated primary current should be at least 1000 for good accuracy under normal conditions if silicon steel is used. In high-range current transformers this condition is met by the use of a single primary conductor running through the center of the core opening. A transformer of this type has the great advantage that when subjected to severe overloads there is no mechanical force tending to distort the primary. Moreover, in high-voltage circuits a single-turn transformer can be made by slipping a core and secondary winding over the bushing of a power transformer or oil switch, thus saving the cost of additional insulation. In ratings below 600 amp the ratio error and phase angle of single-turn transformers become large unless some special means is provided for reducing them.

The ratio error at any chosen burden may be made small for one value of current by choosing a number of secondary turns slightly less than that corresponding to the nominal ratio of the transformer. The phase angle for a given burden can be reduced somewhat by providing a closed tertiary circuit of suitable impedance.

Much greater improvement applicable over a considerable range of current, burden, and frequency can be obtained by certain other procedures. One of these is the use of a **two-stage current transformer** (see paper by Brooks and Holtz, Trans. A.I.E.E. 41, p. 382, 1922), which is provided with an auxiliary magnetic circuit encircled by primary and secondary windings having a turn ratio equal to the nominal transformer ratio. Any departure from perfect performance of the main (or first-stage) unit induces a corrective current in a third winding on the auxiliary core. This corrective current, passed through an auxiliary current coil in a secondary instrument, will add its effect vectorially to that of the main current in the regular instrument coil, with the result that the effective ratio of primary current to the vector sum of the main and auxiliary secondary currents is very close to the nominal value. By the use of a suitably adjusted impedance network, two-stage transformers can be used with ordinary instruments and meters having single current windings.

Another method for improving the accuracy of current transformers is the use of **special nickel-iron alloys** (such as hipernik; see paper by Spooner, Trans. A.I.E.E. 45, p. 701, 1926) which have very low losses and high permeability. The errors are reduced

roughly in proportion to the losses, and high accuracy with low rated ampere-turns or moderate accuracy with a very small and light transformer can be obtained.

A third scheme is to provide a hole through the core splitting the magnetic circuit into two parallel paths over part of its length (see paper by Wilson, Trans. A.I.E.E. 48, p. 783, 1929). A few turns of the secondary circuit are wound through this hole and cause one path to operate at a flux density different from that in the other. A change in the current changes the relation between the reluctances of the paths, and the effective secondary linkages can be made to vary in such a way as to maintain a nearly constant ratio. A short-circuited turn through the hole tends to compensate the phase angle in a similar fashion. A saturated-core reactor of suitable design in parallel with the secondary burden can be used with similar results.

When a short circuit occurs on the line in which a current transformer is connected the primary current may momentarily attain many times the rated value. The design of the primary winding should be such that the transformer will not be damaged by the mechanical or thermal effects of specified overloads. If the design is such that the core is carried well up to saturation at these large currents, the secondary current will not increase in proportion to the primary current. Such a characteristic is often desirable since the secondary instruments and relays are thus spared much of the shock of the short circuit, though the increase in secondary current may be ample to cause the relays to function. In other applications, however, it is important that the current transformer maintain its ratio reasonably constant even on severe overloads. Transformers can be designed to have either type of characteristic.

It is sometimes desired to measure the current in a cable without cutting it to insert the primary winding of a transformer. This can be done by the use of a current transformer, the core of which is made in two parts hinged together, and provided with a secondary winding. Such a transformer can be clamped around the cable which thus forms a single-turn primary winding. Although not capable of very high accuracy, such transformers are very useful, in approximate measurements; for example, of the current taken by motors, the distribution of load among transformers banked in parallel, etc.

Most portable current transformers and certain types of switchboard transformers are provided with two or more sections of primary winding which can be connected in series or in parallel, to give various primary ranges. The use of such switchboard transformers makes it possible to take care of growth or redistribution of the station loads without replacing the transformers.

Certain types of current transformers, especially oil-filled high-voltage transformers, are made with duplicate cores and duplicate secondary windings, placed in a common oil tank and linked with the same primary winding. Such "double-secondary" transformers constitute in effect two transformers, one of which can be used with a light burden for accurate metering, while the other supplies relays or other control equipment of higher burden. This construction avoids the duplication of the expensive high-voltage bushing and the oil tank.

TESTING CURRENT TRANSFORMERS FOR RATIO AND PHASE ANGLE.

General. For accurate measurements the ratio error and the phase angle may not be negligible. It is also possible for damage to the transformer windings to be caused by surges, overloads, or other disturbance, and it has therefore become the practice of many power companies and the rule of a number of public utility commissions to require the periodic testing, at installation and at intervals of 5 or 10 years thereafter, of all instrument transformers used in important metering installations.

If the core of a current transformer becomes permanently magnetized, as by the passage of direct current through its winding or by the opening of its secondary circuit while primary current is flowing, the ratio and phase angle may be seriously changed. The original values may be restored by **demagnetizing the core.** This is conveniently done by sending an alternating current of 5 amp through the secondary winding, while the primary is open, and gradually reducing this current to zero. An alternative method is to send rated current through the primary winding while the secondary is connected to a resistance of several hundred ohms and gradually to reduce this resistance to zero.

Methods of test fall into two classes, direct and relative. In the former method the ratio and phase angle of a single transformer are determined directly; in the latter the transformer under test is compared with a standard transformer of the same nominal range, the ratio and phase angle of which are already known as the result of some previous test. In general, relative methods are simpler, quicker, and more convenient. Direct methods can be made more accurate but are usually less convenient and require the use of more sensitive and hence more delicate equipment. They are, however, a necessary link in the chain of measurement. Equipments for making direct measurements on instrument transformers are maintained in the laboratories of the National Bureau of

Standards, of certain state public utility commissions, of the larger manufacturing companies, and of a few of the larger power companies. Relative testing methods are regularly used by other state commissions and by a large number of power companies, their standard transformers being checked at regular intervals by reference to one of the direct equipments.

Direct Methods for Ratio and Phase Angle. In these methods the IR drops in two known non-inductive resistors, carrying the primary current and the secondary current respectively, are adjusted to be equal and opposite. The ratio of currents is then the reciprocal of the ratio of resistances. The value of the phase angle is obtained from the value of mutual inductance or of capacitance required to bring the two IR drops into exact opposition.

These direct null methods can be forced to a precision of setting of 0.01 per cent, which is enough to reveal unavoidable changes in the performance of most current transformers caused by self-heating, magnetization, etc. The principal sources of error are uncertainties as to the residual inductance and the resistance at rated current of the primary resistor and the effects of the stray magnetic field produced by the large primary current of the transformer under test. The design of suitable non-inductive primary resistors becomes very difficult for currents above 1000 amp. The testing of current transformers of high ranges is probably best done by a relative method, using as a standard a special transformer provided with a number of equal sections of primary windings. Such a transformer can be standardized by a direct method on a low range with the sections of primary winding in series and then used as a standard of higher range with its sections in parallel. The ratio can be considered as strictly inversely proportional to the number of series primary turns, and the phase angle as strictly constant, provided only that each section of the primary winding carries its equal share of the total current when the sections are in parallel, or that all sections have equally close magnetic coupling to the secondary winding. This latter condition can be very closely approximated by the use of a ring core with a uniformly distributed secondary winding. This same principle is made use of in the Baker test-ring method for the direct testing of current transformers.

Relative Methods for Ratio and Phase Angle. Of the relative methods the simplest is that in which the primary windings of the test and standard transformers are connected in series while each secondary winding is connected to one of a pair of similar measuring instruments, of which the difference in the readings gives directly the difference in the two transformers. If only the ratio is desired the two instruments may be 5-amp ammeters. If a phase-angle comparison also is desired, two wattmeters or two watthour meters are used. In any case the effect of errors in calibration of the instruments can be almost entirely eliminated by interchanging them and using the mean of the two sets of readings thus obtained. The wattmeter or watthour-meter readings made with the voltage circuits excited in phase with the primary current give directly a comparison of the ratios of the two current transformers. The readings made with the voltage circuits excited in quadrature with the current give a measure of the difference in phase angle of the two transformers.

The accuracy of methods of this type is limited by the precision of reading the ammeters or wattmeters and becomes very poor at low currents. By using two watthour meters and allowing the registration to accumulate over a longer time at small currents the precision can be considerably increased.

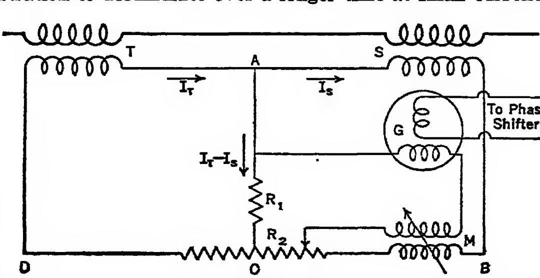

FIG. 35

The advantages of the relative method of test are much greater when balance methods are used. As indicated in Fig. 35, if the primary windings of two transformers T and S are connected in series, the secondary windings may also be connected in series so that their induced emf's aid in sending current through the main circuit $ABCD$. If for instance the transformer under test T has a smaller ratio (and hence a larger secondary current I_T) than does the standard transformer S, the excess secondary current $I_T - I_S$ will flow through the bridge circuit R_1 between points A and C. This vector difference in current may be measured directly by inserting in R_1 one coil of a separately excited

electrodynamic instrument (a 1-amp wattmeter fixed coil or a 30-volt wattmeter moving coil is convenient; a 10-amp ammeter should be first tried as a precaution against damage to the wattmeter if the transformers are connected with the wrong polarity). The difference in ratio and the phase angle (in radians) of the two transformers are given directly with ample accuracy by the ratio of the in-phase and quadrature components respectively of the difference in current, to the total secondary current of either transformer.

A more convenient modification of this method is to measure the vector difference $(I_T - I_S)$ in current by a null method. This is done by inserting a fixed resistance R_1 (of, say, 0.2 ohm) in the bridge circuit AC and balancing the IR drop of the difference current in it against the sum of the drop of the secondary current flowing in a slide wire of resistance R_2 and the emf induced in the secondary of the mutual inductor M. The detector at G is thus brought to a zero deflection and its calibration need not be known. The difference in ratio of the two transformers is then R_2/R_1, and the phase angle (in radians) is $\omega M/R_1$. Portable test sets (known as the Silsbee Current Transformer Test Set) embodying the principles of Fig. 35 are widely used for routine current transformer testing.

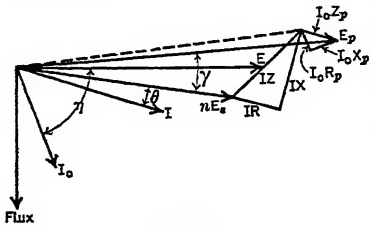

Fig. 36

RATIO AND PHASE ANGLE OF POTENTIAL (VOLTAGE) TRANSFORMERS. The relations of the quantities involved are shown in the vector diagram, Fig. 36.

$$\text{Ratio} = \frac{E_p}{E_s} = n\left[1 + \frac{IR\cos\theta + IX\sin\theta}{nE_s} + \frac{(IR\sin\theta - IX\cos\theta)^2}{2n^2E_s^2} + \frac{I_0R_p\cos\eta + I_0X_p\sin\eta}{nE_s}\right] \quad (15)$$

$$\text{Phase angle } \gamma \text{ in minutes} = \frac{3438}{E_p}[IR\sin\theta - IX\cos\theta + I_0R_p\sin\eta - I_0X_p\cos\eta] \quad (16)$$

where n = ratio of the primary turns to the secondary turns.
R and X = equivalent resistance and reactance of the transformer, referred to the primary side.
R_p and X_p = resistance and reactance of the primary winding.
E_p = primary impressed voltage reversed.
E_s = secondary terminal voltage.
E = primary induced voltage.
$I = I_s/n$ = load current in the primary winding, I_s denoting the secondary current.
I_0 = exciting current.
η = angle by which secondary induced voltage leads exciting current.

It is assumed that
$$\frac{R_p}{R} = \frac{X_p}{X} \quad (17)$$

because the reactance of the primary and secondary windings cannot be directly determined. The third term within the brackets in the expression for the ratio is very small and can be omitted with very little error. Hence it is evident that at constant power factor and constant secondary voltage the ratio and phase angle will vary linearly with the secondary current. Also, if the impedance of the burden is kept constant as the voltage is changed the ratio and phase angle of high-grade voltage transformers are found to change only to the very slight extent which results from lack of exact proportionality between I_0 and E_s.

The phase angle γ of a voltage transformer, i.e., the angle between the primary terminal voltage and the reversed secondary terminal voltage, may range from a negative angle (reversed secondary voltage lagging behind primary voltage) to a considerable positive angle (reversed secondary voltage leading primary voltage), depending on the exciting current, power factor, and impedance of the secondary burden and the impedance of the transformer windings. Under the no-load condition this angle is nearly always positive, and at high core densities where the exciting current is large and of very low power factor, it may be very large. The general tendency of non-inductive secondary burdens is to cause γ to vary in the negative direction (secondary voltage to lag) and of inductive (lagging current) burdens to cause it to vary in the positive direction (secondary voltage to lead). It is frequently possible to bring γ practically to zero for a single voltage and burden by adding a non-inductive burden in suitable amount.

SPECIAL VOLTAGE-TRANSFORMING DEVICES. For high-voltage circuits the size and hence the cost of voltage transformers of the conventional type increases very rapidly (roughly in proportion to the square of the rated primary voltage) because of the large amount of insulation required and the need for using in the primary winding a size of wire of reasonable mechanical strength, much larger than would be required to carry the load current. To avoid this expense European manufacturers have developed several alternative types of construction. See Bibliography, papers by Imhof, Keinath, and Goldstein; for a summary of these developments in English see chapter 24 of book, Industrial Electrical Measuring Instruments, by Edgcumbe and Ockenden.

TESTING VOLTAGE TRANSFORMERS FOR RATIO AND PHASE ANGLE. The phase angle and the departure from nominal ratio are usually less in voltage transformers than in current transformers, but are not always negligible. Methods for testing voltage transformers also can be classified as direct or relative, the former being more accurate but slower and requiring more expensive and delicate equipment. The relative methods have the further advantage that the circuits which the operator has to handle are completely insulated from the high voltage, which is not true of direct methods.

Resistance Method. This method requires the use of a high-resistance non-inductive resistor which can be connected across the line supplying the full rated primary voltage of the transformer under test. The current flowing in the resistor is usually 0.1 or 0.05 amp. The secondary voltage of the transformer under test is balanced against the IR drop in a known portion of the high resistance at its grounded end. The ratio of primary voltage to secondary voltage is then given by the ratio of the total resistance to the resistance of the portion across which the secondary is balanced. The effect of the transformer phase angle can be balanced by inserting an adjustable self inductor in one portion of the high-resistance circuit, by shunting part of the other portion with a condenser, or by connecting a mutual inductor with its primary in series with the resistor and its secondary in series with the detector. An alternative procedure for determining phase angle is first to make the ratio balance with an electrodynamic instrument excited in phase with the applied voltage and then to measure the phase angle by noting the deflection of a second calibrated electrodynamic instrument excited in quadrature.

Because of the high applied voltage this method is capable of very great precision even when used with insensitive and rugged detectors. It also has the advantage that the transformer can be tested with zero burden. The principal sources of error arise from the self-heating of the main resistor and from the effects of stray capacitance between sections of the main resistor and ground. For voltages above 5000 volts it is essential to minimize these effects by subdividing the resistor into a number of sections, each enclosed in a metal shield. An auxiliary guard circuit (usually having the same resistance as the main resistor) is connected in parallel across the line. Each shield of the main resistor is connected to a tap on the guard circuit so located that the potential of the shield is midway between the potentials of the ends of that section of the main resistor which it encloses. Resistors of this type can be made for use up to 50 kv, and by using a set of autotransformers in place of the guard resistance an equipment has been built for 132 kv.

Capacitance Method. In this method, which is applicable above 10 kv, the secondary of the transformer under test is connected in series with the primary, at its grounded end, with such polarity that the difference of potential between the extreme ends of the circuit thus formed is greater than the potential difference applied to the primary alone. A circuit consisting of an air capacitor of small capacitance but of high voltage rating, in series with an adjustable mica or air capacitor of much larger capacitance but of low voltage rating, is connected across the extreme terminals. The detector is connected between the junction of the two capacitors and the (grounded) junction of the two transformer windings. When a balance has been obtained by adjustment of the low-voltage capacitor the ratio of the transformer voltages is equal to the ratio of the capacitance of the low-voltage capacitor to that of the high-voltage capacitor. The effect of phase angle can be balanced by a mutual inductor which has its secondary in series with the detector while its primary, in series with a resistance of several thousand ohms, is connected across the secondary of the transformer under test.

The capacitance of the mica capacitor can be measured by the usual methods, and the effect of its phase angle on the apparent phase angle of the transformer can readily be allowed for. The capacitance of the high-voltage air capacitor may be computed from its dimensions or measured at audio frequency in terms of other capacitances or inductances. An alternative procedure is to determine at a moderate voltage the ratio of the two capacitances by comparison with a voltage-transformer testing equipment of the resistance type, and then to use this ratio in later testing work at higher voltages, beyond the range of the resistance equipment.

Another method of extending the range of testing equipment is to use a standard voltage transformer the primary winding of which consists of a number of sections of nearly equal impedance which also have nearly equal magnetic effects on the core and secondary. The ratio and phase angle of such a transformer may be determined by resistance equipment when the sections of the primary winding are in parallel, and the transformer may then be used as a standard in some relative testing method, with the primary sections in series. Under ideal conditions the phase angle would be the same on both connections and the ratio would be proportional to the number of primary turns. The principal departure from these ideal relationships would be expected to result from the effect of the stray capacitance between the sections of the primary winding. Careful measurements on several transformers at the National Bureau of Standards have shown these capacitance effects to be less than the error of measurement in all the cases examined.

Relative Methods. The use of two voltmeters, two wattmeters, or two watthour meters connected respectively to the standard and the test voltage transformers offers, of course, a possible method of test analogous to those used with current transformers. These methods are little used, however, because it is simpler to compare the two transformers by an opposition method. In this method (see paper by Brooks, Bull. Bur. Standards, 10, p. 419, 1914), the primary windings of the two transformers are supplied in parallel at rated voltage. The secondary windings are connected in series opposition, and the small difference in voltage is measured by a suitable separately excited electrodynamic instrument. This instrument may be a low-range wattmeter or one having fine-wire windings on both fixed and moving coils as in the Weston "comparator voltmeter." The difference in voltage as read with the instrument excited in phase with the supply voltage, when divided by the secondary voltage of either transformer, gives the difference in ratio factor of the two transformers; the corresponding quotient obtained when the excitation is in quadrature gives (in radians) the difference in the two phase angles.

This procedure can be made into a null method of high precision. A resistance of about 2000 ohms is connected across the secondary of the transformer which has the higher secondary voltage. The secondary voltage of the other transformer is then balanced against the IR drop in this resistance between one end and an adjustable sliding tap near the other end. The phase angle can be balanced by using a mutual inductor, the primary of which, in series with about 4000 ohms, is connected across the secondary of the standard transformer while the secondary of the inductor is in series with the detector. If the standard transformer is chosen to have a ratio, say, 2 per cent lower than nominal, the two measuring circuits will always be connected to it and will not constitute a burden on the transformer under test. This method avoids the error in reading any indicating instruments, and if the transformers have nearly the same ratio even a large error in the 2000-ohm resistance has a negligible effect on the result. The main limitation on the accuracy, therefore, lies in the calibration of the standard transformer. Another and somewhat similar relative method is used in the Leeds & Northrup voltage transformer testing set.

SECONDARY VOLT-AMPERE RATING OF INSTRUMENT TRANSFORMERS. Current transformers intended for use with a single measuring instrument usually have a secondary rating of 25 volt-amperes, and for use with more than one measuring instrument a rating of 50 volt-amperes, at rated secondary current.

Voltage transformers usually have a rating of 50 or 200 volt-amperes at rated secondary voltage.

COMPENSATION FOR RATIO ERROR. By properly proportioning the number of turns in the windings of a current transformer, it is possible to raise the secondary current to overcome the ratio error, with a given condition of burden. It is usual to compensate a current transformer for one-half its rated secondary burden, with secondary power factor of 80 per cent and frequency of 60 cycles.

The actual ratio of turns in a voltage transformer differs from the marked ratio by an amount sufficient to make up the voltage drop in the transformer at a specified burden. Voltage transformers are usually compensated for one-fifth their volt-ampere rating, with a secondary power factor of 80 per cent, and at rated frequency. The effect of phase displacement, however, cannot be compensated for, as it depends not only on the constants of the transformer itself, but on the power factor of the burden on the voltage transformer, and on the power factor of the load which is being measured with the help of the transformers.

ACCURACY OF INSTRUMENT TRANSFORMERS. Fig. 37 gives curves typical of the performance of modern current transformers under operating conditions as indicated in the following schedule:

Curve	Grade of Transformer	Frequency	Burden	
			Ohms	Microhenrys
A	Small and cheap	60	0.68	920
B	Average	60	0.68	920
C	"	60	0.97	4020
D	"	25	0.68	920
E	Excellent	60	0 68	920

The burden for curve *C* is typical of a relay circuit; that for the other curves includes a Silsbee current transformer testing set and indicating instruments. For a watthour meter only, or for indicating instruments only, the burden would be materially less.

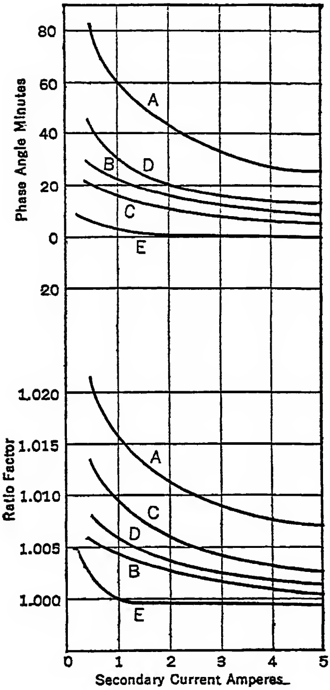

Fig. 37

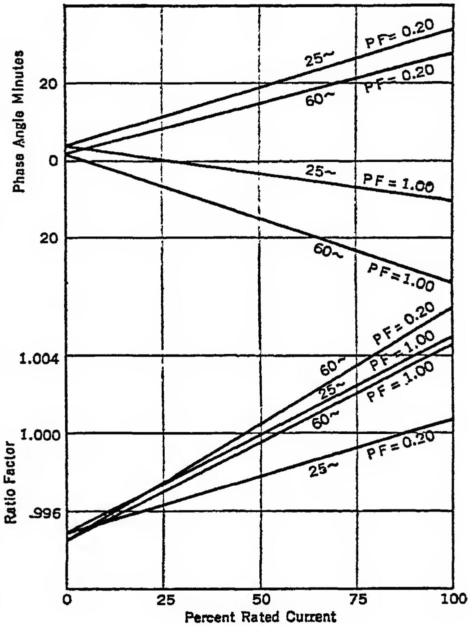

Fig. 38

Fig. 38 gives performance curves of a typical voltage transformer, ratio and phase angle being plotted as ordinate against percent of rated current as abscissa, for the operating conditions indicated on the curves.

14. ELECTROMETERS

GENERAL. An electrometer is primarily an instrument for measuring potential differences, but under certain conditions may also be used as a wattmeter; in the latter case it is usually called an electrostatic wattmeter. The deflection of the instrument is due to the attraction or repulsion of electrostatic charges. An electrometer may be used for either d-c or a-c measurements.

There are many forms of electrometers. On account of the care required in its use, the ordinary quadrant electrometer is seldom employed except for laboratory purposes, but various modifications of the electrometer provided with pointer and scale so as to be direct reading are used commercially for high-voltage measurements. Such instruments are known as electrostatic voltmeters.

The advantage of the electrometer over the galvanometer or electrodynamometer is that it takes no current when used for d-c voltage measurements. Owing to its capacitance, however, it does take a certain amount of charge which should always be allowed for if the capacitance of the electrometer is appreciable compared with any other capacitance which affects its reading. Also, when used for a-c measurements, the charging current taken by the electrometer should be allowed for, if appreciable.

APPLICATIONS. Electrometers are used in the measurement of the very small currents, 10^{-8} amp or less, dealt with in measuring insulation resistance and gaseous ionization, especially in studying x-rays and atmospheric electricity; in chemical work when electrode potentials are used to indicate the end points of certain titrations; and in investigations of static electricity. Electrostatic wattmeters are used in measuring small amounts of power at low power factor and high voltage, as in cable testing, and by the (British) National Physical Laboratory as a basic transfer instrument for the measurement of a-c power.

QUADRANT ELECTROMETER FOR VOLTAGE MEASUREMENTS. In this common type (Fig. 39) the two opposite quadrants a and a' are permanently connected together as are b and b'. Each pair is insulated from the other pair and from the case. The "needle" n (a light aluminum vane shaped like the figure 8) is suspended symmetrically between the upper and lower faces of the quadrants, by a fiber of silvered quartz, and is insulated from the case and quadrants. The complete expression for the electrostatic torque τ acting on the moving system is

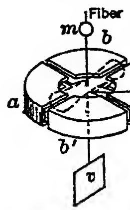

FIG. 39

$$\tau = \alpha V_n^2 + \beta_a V_a^2 + \beta_b V_b^2 + \gamma_a V_n V_a + \gamma_b V_n V_b + \delta V_a V_b + \eta_n V_n + \eta_a V_a + \eta_b V_b + \eta_0 \quad (18)$$

where V_n, V_a and V_b are the potentials, relative to the case, of the needle and of the quadrant pairs a and b respectively. The coefficients η result from the contact potentials of the metals used and are generally small. The effect of η_0 is merely to stress the suspension slightly when the zero reading is made. The other η terms, if appreciable, can be eliminated by suitable reversals of polarity. The coefficient δ is usually extremely small. If the instrument is perfectly symmetrical, α is also zero and

$$\beta_b = -\beta_a = \frac{\gamma_a}{2} = -\frac{\gamma_b}{2} = \kappa \quad (19)$$

and for these conditions the torque becomes

$$\tau_s = \kappa(V_a - V_b)\left(V_n - \frac{V_a + V_b}{2}\right) \quad (20)$$

In general the coefficients α, β, etc., will depend on the angular position of the needle as well as upon its size, shape, etc. If, for instance, the coefficient $\alpha = b\theta$ and the stiffness of the suspending fiber is U, the other coefficients having the values given in (19), the deflection is given by the relation

$$\theta = \frac{\kappa}{U - bV_n^2}(V_a - V_b)\left(V_n - \frac{V_a + V_b}{2}\right) \quad (21)$$

When a small difference of potential is to be measured, it is usually applied between the quadrants, while a suitable larger potential V_n from an auxiliary battery is applied to the needle. This is known as the "heterostatic connection." The term $\frac{V_a + V_b}{2}$ in eq. 21 is then negligible, and it will be seen that the deflection will be proportional to the first power of the measured difference $V_a - V_b$ and will increase rapidly with V_n, both because V_n is a factor in the numerator and because (if b is positive) an increase in V_n decreases the denominator. For too large values of V_n the instrument becomes unstable. In the Compton electrometer one quadrant is made adjustable so that b can be given any desired value.

When relatively large voltages are to be measured, V_a and V_n are made zero and the voltage to be measured is applied between the b quadrants and the case. This is known as the "idiostatic connection". The deflection is then proportional to the square of the applied voltage.

EXTENSION OF RANGE OF ELECTROMETER BY USE OF AUXILIARY CAPACITORS. By connecting the potential difference to be measured across two condensers in series and measuring the voltage across only one of them, the instrument

may be used for the measurement of high voltages of practically any magnitude. The connections are as shown in Fig. 40. If the condensers have no leakage, then

$$V = V_1 \frac{C_1 + C_2 + c}{C_2}, \tag{22}$$

where V_1 is the voltage read by the electrometer, C_1 and C_2 the capacitances of the two condensers, and c the capacitance of the condenser formed by the electrometer quadrants and needle. If C_1 and C_2 are large compared with c, then c may be neglected, but the larger C_1 and C_2 the greater will be the charge (and therefore the charging current, in case of an a-c measurement) taken by the measuring circuit.

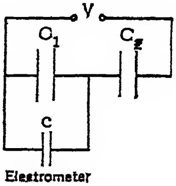

FIG. 40

QUADRANT ELECTROMETER AS ELECTROSTATIC WATTMETER (Fig. 41). The quadrant electrometer may be used to measure, with a fair degree of precision, very small amounts of power, of the order of 1 watt, when the voltage giving this power is 5000 volts or more. It therefore serves as a very convenient means of measuring the power loss in small samples of insulating materials at high voltages. See Bibliography.

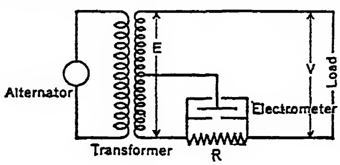

FIG. 41

STRING (FIBER) ELECTROMETERS. In this class of instruments the moving element consists of one or two fine fibers (usually of silvered quartz) held taut by a thicker quartz filament. Each fiber moves sideways under the influence of the electrostatic forces, and is viewed through a microscope provided with a scale in the eyepiece. Instruments of this class have the advantage of being quickly responsive and well damped and of having relatively low capacitance. The scale length and voltage sensitivity, however, are rather less than can be obtained with the quadrant type.

15. ROTARY VOLTMETER FOR HIGH D-C VOLTAGES

The **rotary voltmeter** ("generating voltmeter") for measuring high d-c voltages consists of an armature formed of two semicylindrical metal plates rotating in the electrostatic field between two electrodes which are connected to the points between which the voltage is to be measured. The two plates are connected through a two-part commutator to a galvanometer. The armature is rotated by a motor at a known constant speed. The current through the galvanometer varies directly as the voltage between the two inducing electrodes. The results of a calibration made at low and moderate voltages may therefore be extrapolated to high voltages, provided the electric field in the vicinity of the rotor is not distorted by space charges such as might result from corona at high voltages. The range is limited only by the clearances between live parts. One terminal of the galvanometer is grounded, and the galvanometer may be located at any desired distance from the high-voltage circuit. The sensitivity may be varied by altering a shunt around the galvanometer.

16. SPARK GAPS FOR MEASURING HIGH VOLTAGES

GENERAL. The voltage (crest value) required to break down a given gap depends principally upon: (1) the shape, size, and arrangement of the electrodes; (2) the presence of other conductors or insulators in the vicinity of the gap; (3) the time of application of the voltage; and (4) the temperature, pressure, and humidity of the air. Other factors of lesser significance are: (1) the composition and surface condition of the electrodes; (2) the circuit arrangements and constants; (3) the wave form and frequency of the voltage; (4) the extent to which the air in the gap is ionized; (5) the degree of irradiation of the spheres. Used under specified conditions, the spark gap is a commercially accurate device for measuring crest voltage in the testing of insulating materials and insulating structures.

In American practice the **needle gap** and the **sphere gap** have been used. The needle gap has the advantages of being readily extemporized and of being several times as long (for a given voltage) as the sphere gap, but its sparking distance is appreciably affected by variation of atmospheric humidity; that of the sphere gap, within the useful range of gap length, is only very slightly affected. The needle gap is now regarded as inferior to the sphere gap. The former A.I.E.E. sphere-gap tables have been extended down-

ward to include spheres 20 mm in diameter to cover the range 10 to 30 kv, rms, for which A.I.E.E. standards formerly recommended the needle gap.

For higher voltages the sphere gap has the advantages of occupying less space, of freedom from time lag, and of breaking down with a sharply defined spark discharge without previous formation of corona, provided the gap length does not greatly exceed the sphere diameter. The sphere gap has the further advantage that the electrodes do not have to be renewed after each discharge, as they do with the needle gap.

CONSTRUCTION OF SPHERE SPARK GAP. Fig. 42 shows the arrangement recommended by Farnsworth and Fortescue. The top sphere is stationary but slightly adjustable in height so as just to make contact with the lower sphere when it is set for zero separation. The lower sphere is mounted on a piece of brass tubing which carries a threaded bushing on its lower end. This bushing works on a carefully threaded rod having a pitch of two threads per centimeter. The bushing being graduated to fiftieths on its circumference, separation may be measured to the nearest 0.01 cm directly.

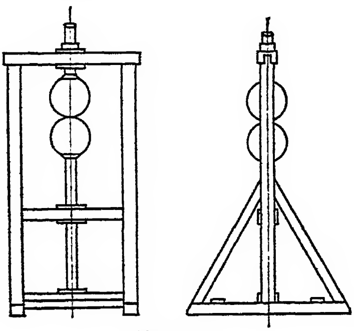

Fig. 42

The following specifications for the two forms of gap are taken from A.I.E.E. Standards No. 4 (May, 1928), Measurement of Test Voltage in Dielectric Tests.

NEEDLE GAP. The needle spark gap shall be between new sewing needles, supported axially at the ends of linear conductors at least twice as long as the gap. There must be a clear space around the gap for a radius at least twice the gap length.

The sparking distances in air between No. 00 double-long sewing-needle points for various rms sinusoidal voltages shall be assumed to be as shown in Table III.

Table III. Needle-gap Spark-over Voltages

At 25 deg cent and 760 mm barometric pressure.

Sinusoidal rms kilovolts	Millimeters	Sinusoidal rms kilovolts	Millimeters
10	11.9	35	51
15	18.4	40	62
20	25.4	45	75
25	33	50	90
30	41		

The values in this table refer to a relative humidity of 80 per cent. Variations from this humidity may involve appreciable variations in the sparking distance.

A.I.E.E. STANDARD SPHERE SPARK GAP. The standard sphere spark gap shall be between two suitably mounted spheres. No extraneous conducting body, other than the supporting shanks, should be nearer the gap than twice the sphere diameter. Insulating bodies, such as supporting structures, should not be nearer than one sphere diameter to the gap. The shanks should not be greater in diameter than $^1/_5$ the sphere diameter. Metal collars, etc., through which the shanks extend, shall be as small as practicable and shall not, during any measurement, come closer to the spheres than the maximum gap length used in the measurement. The sphere curvature measurement by a spherometer should not vary more than 1 per cent from that of a true sphere of the required diameter. In using the spherometer to measure curvature, the distance between the points of contact of the spherometer feet shall be within the limits indicated in Table IV.

Table IV. Spherometer Specifications

Diameter of Sphere in mm	Distance between contact points, in mm	
	Maximum	Minimum
20	12.5	7.5
62.5	35	25
125	45	35
250	65	45
500	100	65
750	135	80

NOTE.—This table has been given instead of the A.I.E.E. table in Standard No. 4, because the latter is now (1936) in process of revision, and the I.E.C. figures are known to be more accurate. For sine waves, the rms voltage is 0.707 times the crest voltage. For example, 500 kv crest voltage corresponds to 353.5 rms voltage, the sparking distance being 236 mm with 500 mm spheres.

The standard sphere gap should be set up for use in a space comparatively free from external dielectric fields. Care should be taken that conducting bodies forming part of the circuit, or at circuit potential, are not so located with reference to the gap that their dielectric fields are superimposed on that of the gap; for example, the protective resistor should not be arranged so as to present large surfaces near the gap, even at a distance of twice the sphere diameter. If one sphere is grounded the spark point of this sphere should be not less than 5 and not greater than 10 times its diameter from any grounded surface. When sphere gaps are used as specified, with corrections properly applied, the accuracy of voltage measurement should be approximately 2 per cent.

SPHERE-GAP SPARKING DISTANCES. The sparking distance between spheres for various crest voltages shall be assumed to be as shown in Table V, when the air density is that corresponding to a barometric pressure of 760 mm mercury and a temperature of 25 deg cent. For any other air density the voltage at which the gap breaks down, for any given spacing, is equal to the breakdown voltage for this spacing at standard pressure and standard temperature multiplied by the correction factor given in Table VI. The relative air density is found from the formula:

$$\text{Relative air density} = \frac{0.392b}{273 + t} \tag{23}$$

where b = barometric pressure in millimeters and t = temperature in degrees centigrade. To determine the gap spacing for a required spark-over voltage, divide the required voltage by the correction factor obtained from Table VI and use the new voltage thus

Table VI. Air-density Correction Factors for Sphere Gaps

Relative Air Density	Diameter of Standard Spheres in Millimeters

obtained to find the corresponding spacing from Table V, using a graph of the latter, if more convenient.

PRECAUTIONS IN SPHERE-GAP MEASUREMENTS. With the exception of its own support or parts, all objects at ground potential should be separated from all live parts of the apparatus under test by a distance in inches not less than the quotient obtained from dividing by 5000 the maximum test voltage which will be applied.

As a precaution against overvoltage oscillations, and to limit the resulting current at the time of breakdown, a non-inductive resistance of about 1 ohm per volt of test voltage to be used should be inserted in series with the sphere gap. If the test is made with one terminal grounded, the entire resistance should be in series with the non-grounded electrode; if neither terminal is grounded, one-half of the resistance should be in series with each electrode. In either case this resistance shall be electrically as near the spark gap as possible and not in series with the apparatus under test. Water-tube resistors are used for this purpose. Carbon resistors of high resistivity should not be used because their resistance may become very low at high voltages.

The sphere gap should be set up for use in a space comparatively free from external dielectric fields. Conducting bodies forming part of the circuit, or at circuit potential, should not be so located with reference to the gap that their dielectric fields are superimposed on that of the gap. For example, the protective resistor should not be arranged to present large surfaces toward the gap, even at a distance of twice the sphere diameter.

If one sphere is grounded the spark point of this sphere should be not less than 5 and not more than 10 times its diameter from any grounded surface.

It is important that the surfaces of the spheres be kept free from dust and moisture, and that the spheres do not become heated appreciably by repeated discharges.

Irradiation of the gap with ultraviolet light considerably reduces the scattering of the values of breakdown voltage, and is particularly useful with high frequencies and essential with impulse voltages. For this purpose an open arc or a quartz mercury-vapor lamp may be used.

The sphere gap is more sensitive than the needle gap to momentary rises of voltage, and the voltage required to spark over the gap should be obtained by slowly closing the gap under constant voltage, or by slowly raising the voltage with a fixed setting of the gap.

For additional detailed information on the characteristics of the testing equipment, its arrangement, and methods for voltage control, consult the latest edition of A.I.E.E. Standards for the Measurement of Test Voltage in Dielectric Tests.

17. CORONA VOLTMETER

The corona voltmeter, originated by Whitehead, has certain advantages over the sphere gap for the measurement of crest voltages. For a discussion of this instrument and a bibliography, see Brooks and Defandorf, *Bur. Standards J. Research*, vol. 1, p. 589, 1928; reprinted as Bur. Standards Research Paper 21.

18. OSCILLOGRAPHS

GENERAL. An oscillograph is essentially an instrument for observing rapid variations in voltage or current. These variations are automatically plotted (usually against time) on a suitable screen or (if a permanent record is desired) on a photographic film.

The moving system of the oscillograph may be a conducting loop or an iron vane (the galvanometer oscillograph); a single conducting filament (Einthoven's string galvanometer); two insulated conducting filaments (the electrostatic oscillograph); or an electron beam (the cathode-ray oscillograph). The moving system is situated in a magnetic or electric field and is actuated either by changes in its own current or potential or by changes in the field in which it lies. The inertia of the moving system is kept small in order that it may follow very rapid variations in the phenomenon to be observed. An oscillograph will record without appreciable distortion only those events which have frequencies much less than the natural frequency of its moving element. Distortion of high-frequency harmonics in a wave varies with the type of moving system and with its damping but is generally negligible for frequencies up to $^1/_5$ of the natural frequency of the vibrator.

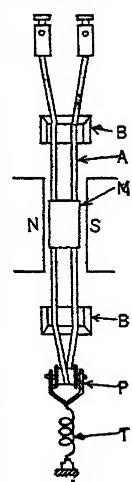

Fig. 43

The **moving-coil oscillograph** is ordinarily used for frequencies up to 2000 cycles per second and, where high sensitivity is required, may be used with a suitable amplifier. The **cathode-ray oscillograph** may be used at any frequency, but its chief application is at frequencies beyond the range of the moving-coil oscillograph. The string galvanometer is useful as an oscillograph at low frequencies where extremely high sensitivity is required.

MOVING-COIL OSCILLOGRAPH. The moving-coil oscillograph is essentially a galvanometer of very short period. It is used for voltage observations with a suitable multiplier, or for current observations with a shunt. Single-phase and three-phase wattmeter oscillograph elements give directly a record of instantaneous power. Current and wattmeter elements are interchangeable in the same mountings.

The vibrator element (see Fig. 43) is usually a loop *A* of very light ribbon of silver alloy or aluminum stretched across ivory bridges *BB* and passed around a pulley *P*. Tension is applied to the loop and may be varied by a spring *T* and screw arrangement attached to the pulley. A small mirror *M* is cemented to the loop between the bridges. The vibrator element with its mounting is immersed in a damping liquid and may be removed from the oscillograph as a unit for repair or replacement. It is placed in the narrow gap between the pole pieces *NS* of a magnet. Older designs use an electromagnet, but recently these have been replaced by small permanent magnets which provide an intense field with a large reduction in weight and with the advantage of requiring no d-c source.

Instead of the carbon arc formerly used, most recent designs use a low-voltage fila-

ment lamp operated at a considerable overvoltage only at the instant of making a photographic record. Light from this source is reflected by the vibrator mirror to the slit of the recording camera or to an oscillating mirror, driven by a synchronous motor, which projects the oscillogram as a standing wave, with linear time scale, on a screen or tracing table. Some models are equipped for simultaneously viewing and photographing a wave. A zero line is obtained on the oscillogram by interposing a small stationary mirror in the light beam just above and in front of the vibrator mirror. A photographic record may be made either with a film wound around a rotating drum or with film or sensitized paper fed at constant speed from a magazine past the camera slit.

Oscillographs are made with from 1 to 9 vibrator elements. Completely self-contained portable instruments are available with from 1 to 6 elements and weighing up to 60 lb. Oscillographs which are completely automatic in operation are made for use in recording switching and other disturbances in power systems. The disturbance may be made to start the record in less than a single cycle. The duration of the record may be predetermined. Such oscillographs are used with magazines taking 200 ft of sensitized paper and will record without attention as many as 100 disturbances.

SENSITIVITY OF MOVING-COIL OSCILLOGRAPH. The sensitivity of the oscillograph vibrator varies greatly with its free period and damping, increasing with greater free period and with diminished damping. The following table gives the sensitivity of some available elements together with their natural (undamped) frequencies.

Table VII. Sensitivity of Oscillograph Elements

Natural Frequency, cycles per second	Sensitivity, radians per ampere
8000	0.2
5000	0.4
3000	1.2
1200	12.0

The resistance of a vibrator element is ordinarily about 1 ohm. The distance from the vibrator mirror to the screen varies in different models from about 25 to 65 cm.

Distortion may occur in the higher-frequency components of an oscillogram since both the sensitivity and the phase displacement of the vibrator with respect to the applied voltage change with frequency.

Assuming unit deflection for a given steady direct voltage, the maximum deflection θ for a sine-wave voltage of any frequency and having the same crest value is given by the formula

$$\theta = \frac{1}{[p^4 + p^2(4N^2 - 2) + 1]^{1/2}} \tag{24}$$

where $p = f/f_r$ is the ratio of the applied frequency to the resonance frequency of the vibrator and $N = n/n_c$ is the relative damping.

The phase displacement of the vibrator with respect to the applied voltage is given by the formula

$$\tan \Phi = \frac{2Np}{1 - p^2} \tag{25}$$

The phase displacement of a harmonic of frequency f_h with respect to its fundamental of frequency f_0 is a measure of phase distortion in an oscillogram. This distortion δ, measured in degrees of the fundamental, is given by the formula

$$\delta = \frac{f_0}{f_h}\Phi_h - \Phi_0 \tag{26}$$

The resonance frequency to be used in these formulas is not that which would be found in air (without appreciable damping) but about half that value. The damping liquid is to some extent moved with the vibrator, adding to its effective inertia and thus increasing its natural period. This increase in period depends on the material of the vibrator element, being about 40 per cent for the usual silver-alloy loop and nearly 60 per cent for aluminum, and should be added to the air-damped period which is usually stated by the manufacturers.

Table VIII gives values computed from the above formulas for a damping (70 per cent of critical damping) which gives nearly the minimum distortion in oscillograms. The symbols are explained above. The last column gives typical values for the nth harmonic ($n = 50p$) of a 60-cycle oscillogram for the element commonly used, having a resonance frequency in air of about 5000 cycles per second.

Table VIII. Performance of Oscillograph Vibrator for Damping Equal to 70 Per Cent of Critical Damping

Ratio of Applied Frequency to Resonant Frequency p	Ratio of Deflection at Applied Frequency to Deflection with Direct Current θ	Phase Displacement of Vibrator in Degrees Φ	Phase Distortion $\frac{0.02}{p}\Phi - 1.60$ in Degrees δ
0.01	1.000	0.80	0.00
0.02	1.000	1.60	0.00
0.1	1.000	8.05	0.01
0.2	1.000	16.2	0.02
0.3	0.998	24.8	0.05
0.4	0.991	33.7	0.08
0.5	0.975	43	0.12
0.6	0.947	53	0.16
0.7	0.905	63	0.19
0.8	0.850	72	0.20
0.9	0.785	81	0.21
1.0	0.714	90	0.20
1.5	0.394	121	0.01
2.0	0.243	137	−0.23

The actual damping of the vibrator element depends on the viscosity of the damping liquid and therefore on its temperature. It can be determined for any particular operating condition with a single observation, as follows: A constant direct voltage is impressed on the element and then suddenly removed. If the element is underdamped it will deflect past its equilibrium zero position and will oscillate about zero. The amount of the first overshoot past zero is measured and its ratio to the initial d-c deflection is computed. If this ratio is x the relative damping is given by the formula

$$N = \frac{-\log_e x}{[\pi^2 + (\log_e x)^2]^{1/2}} = \frac{-\log_{10} x}{[1.86 + (\log_{10} x)^2]^{1/2}} \tag{27}$$

CATHODE-RAY OSCILLOGRAPH. The moving system of the cathode-ray oscillograph is a stream of electrons. It is therefore practically without inertia and will respond equally to any frequency.

In an evacuated vessel (see Fig. 44), electrons emitted from a cathode A are accelerated by a suitable voltage toward an anode B which has a small hole in its center. Those electrons passing through the hole form an "electron beam" of sensibly uniform velocity coinciding with the axis of the tube. The beam passes between parallel metal deflection plates C and strikes a fluorescent screen D where it gives rise to a luminous spot. If a photographic film is substituted for the screen, a latent image (subject to development by ordinary means) appears where the beam strikes the active emulsion of the film. In the presence of an electric or magnetic field at C, at right angles to the axis of the tube, the electrons are accelerated perpendicularly to their direction of motion in the beam, resulting in the deflection of the spot at D. Phenomena to be examined are made to produce such a deflecting field at C. A time axis is supplied to the oscillogram by a second field, perpendicular to the first, and varying in a known manner with time.

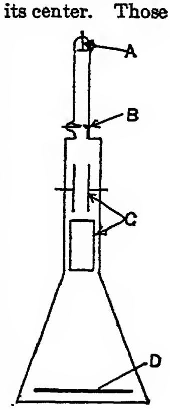

FIG. 44

There are two general types of cathode-ray oscillograph. The **hot-cathode oscillograph** utilizes the electron emission of an incandescent filament. The beam is formed by a relatively low voltage impressed between cathode and anode, usually between 300 and 3000 volts. The **cold-cathode oscillograph** utilizes the electrons freed from the surface of the cathode under positive ion bombardment in a gas discharge tube. The voltage required to generate the beam is high, 50,000 volts or more. In any case the diameter of the beam, and consequently that of the recording spot, are primarily determined by the diameter of the hole in the anode through which the beam passes. This is generally a few tenths of a millimeter.

Sensitivity of Cathode-Ray Oscillograph. The electrostatic sensitivity of the oscillograph is inversely proportional to the cathode-anode voltage and is given approximately by the formula

$$S = \frac{LA}{2VD} \tag{28}$$

in which S = deflection per unit difference of potential between the deflection plates.
L = length of parallel plates (C in figure).
A = distance from plates to screen.
V = potential difference between cathode and anode of the tube.
D = separation of parallel plates.

The sensitivity of available low-voltage (hot-cathode) tubes ranges from 0.2 mm/volt to 1 mm/volt; and for high-voltage (cold-cathode) tubes is about 0.04 mm/volt.

The electromagnetic sensitivity is inversely proportional to the square root of the cathode voltage. It depends on the shape, size, and position of the deflection coils at C and may amount to 1 mm/ampere-turn for a low-voltage tube and 0.1 mm/ampere-turn for a 50,000-volt tube.

Recording Speed. For the low-voltage tube operating at less than 1000 volts, photographic records may be made from the fluorescent screen with a camera only if the trace on the screen be repeated many times. Exposures of some seconds are necessary. The exposure time may be greatly reduced by placing the film in direct contact with the rear surface of the glass window on which the fluorescent material is deposited, but only with a very considerable loss in clearness and definition of the resulting record. For a tube operating at 2000 volts, records of a single passage of the recording spot across the fluorescent screen may be made with a camera when the speed of tracing is less than 10 meters per second.

High-voltage cold-cathode tubes, in which the photographic film is placed in the evacuated chamber and comes in direct contact with the electron beam, are conveniently divided into two classes.

In one type the voltage is applied to the cathode continuously. The electrons are focused on the hole in the anode by a coil situated between the cathode and anode, providing a magnetic field parallel to the axis of the tube. The vacuum in the discharge tube may be controlled by an adjustable gas leak in the side of the tube. Its value is indicated by reading the discharge current with a milliameter. An intense beam is formed in this way and is kept off the photographic plate by an electrostatic field or some suitable beam-blocking device (e.g., the Norinder relay) until the instant the record is to be made. For this type of oscillograph, operating under the best conditions, no practical limit to the recording speed has been found. Records have been made in which the recording spot moved across the film at a velocity of 10^{10} cm per sec ($^1/_3$ of the velocity of light).

In a second type of cold-cathode oscillograph, voltage is applied to the cathode only at the instant the record is to be made. The intensity of the beam is controlled by the gas pressure in the discharge tube. This pressure is read by means of a hot-wire vacuum gage. For a given vacuum, the reading of such a gage depends on the nature of the gas and may be greatly affected by the gases and water vapor given off by the photographic film in the vacuum chamber. Hence the beam intensity is not as closely under control as in the other type of tube and cannot in general be made as great. The maximum recording velocity, depending on the beam intensity, may be made to vary over wide limits as the pressure in the discharge tube is changed. The beam intensity may be made great enough for any except very high recording velocities by ensuring that the cathode is clean and well polished and by adjusting the vacuum in the discharge tube until an intense beam is secured.

A theoretical limiting condition for recording a cathode-ray oscillogram without distortion is that no appreciable change shall take place in the field deflecting the electron beam during the time taken by an electron to pass through the field. This time varies with the voltage used to generate the beam and with the length of the deflection plates. If deflection plates 1 cm long are used in an oscillograph in which the beam is generated at 50,000 volts, this time of passage through the deflecting field is about 10^{-10} sec. Hence this theoretical limit need not be considered in any ordinary engineering applications.

Life of Cathode-ray Oscillograph. The life of the low-voltage hot-cathode oscillograph is determined by the life of the filament and is 200 hours or more. In one type the cathode filament is replaceable. This type requires the continuous use of a pump to maintain the proper vacuum. Other types are adjusted and permanently sealed off when made and must be discarded when the filament burns out.

The electron-beam intensity of the high-voltage cold-cathode oscillograph falls off rapidly as the cathode becomes pitted by the discharge. The discharge tube of the oscillograph must then be replaced, or in some models the cathode may be removed from the tube and polished. When the cathode surface is restored to its initial condition, the oscillograph will again operate satisfactorily. In a cold-cathode oscillograph which is excited only at the instant of recording, a very heavy discharge is necessary to insure an intense beam, and the integrated life of the cathode is a few seconds. This, however,

may amount to a thousand exposures or more when working with high-speed phenomena. The continuously excited discharge tube utilizes a much lower current and secures beam intensity by the focusing action of a magnetic field. The useful life of the cathode is roughly 50 hours.

Circuits Used with Cathode-ray Oscillograph. When using low-voltage, high-sensitivity oscillographs the maximum voltage which may be impressed on the deflection plates is about 50 to 100 volts. The maximum deflection-plate voltage for the high-voltage oscillograph is roughly 1000 volts. Above these limits, imposed by the size of the screen or film, a potential divider, made of resistors or capacitors or some combination of the two, must be used. The choice of a divider requires detailed examination to ensure that two conditions are satisfied; namely, (1) the divider must make no appreciable change in the character of the circuit, that is, the impedance of the divider should be very great compared with that of the circuit; (2) the form of the wave impressed on the deflection plates must be the same as that impressed on the potential divider. Account must also be taken of distributed capacitance, capacitance to ground, and capacitance of the deflection plates; or the parts of the divider must be so arranged that the effect of these capacitances is negligible. The divider must be arranged so that the deflection plates do not differ greatly in potential from their surroundings in order to avoid spurious induced effects in the oscillogram.

In general, capacitance dividers are used for high-frequency and impulse phenomena; resistance dividers are used for low and intermediate frequencies, being limited in their application by two considerations, namely, (1) at high frequencies, unavoidable stray capacitance will change the ratio of voltage division; (2) for impulse work, especially with steep wave fronts, the rate at which potential can change on the deflection plates is limited by the resistance in series with them. The oscillogram recorded may show only the exponential charge and discharge, through a series resistor, of the capacitor formed by the deflection plates, regardless of the form of the voltage wave impressed on the divider. This effect can be reduced by decreasing the resistance of the divider; but, as the resistance decreases, the effect of the divider on the circuit becomes greater.

A number of auxiliary circuits are needed in obtaining cathode-ray oscillograms. The time axis of the oscillogram may be furnished by an oscillator which sweeps the beam repeatedly across the recording film in simple harmonic motion of known frequency. The resulting oscillograms are often difficult to interpret, especially if the phenomenon observed continues over a number of cycles of the timing wave. There is, however, an advantage in simplicity of the circuit, especially if the observed phenomenon is one whose occurrence cannot be predetermined, since the timing motion is continuous and need not be synchronized with the phenomenon. Another type of timing motion much used is a single sweep across the film obtained by impressing the voltage of a capacitor across the timing plates while it is being charged or discharged through a resistor. Such a time scale is exponential. A linear time scale may be obtained by charging the capacitor at a constant rate through a vacuum tube. Such timing circuits must be synchronized with the phenomenon to be observed. A number of relay circuits have been developed for this purpose. If the cathode is continuously excited, another relay circuit may be needed to actuate the beam-blocking device at the proper instant. If the cathode is excited only at the time of recording, the cathode excitation must also be properly timed.

For low-frequency work the switching may be mechanical in the timing and relay circuits. When used with high frequencies or impulse voltages, the timing and relay circuits are usually actuated by the breakdown of spark gaps. This timing may be made to operate in 10^{-8} second.

For details of timing and relay circuits, their calibration and uses, see Bibliography.

STRING GALVANOMETER USED AS OSCILLOGRAPH. The string galvanometer can be used for low-frequency phenomena where extremely high sensitivity is required. It consists essentially of a fine conducting filament, stretched between the pole pieces of a powerful electromagnet. The filament is illuminated through a microscope mounted in a hole bored in one pole piece. Its motion is observed through a second microscope mounted in the opposite pole piece, and it appears as a shadow against a luminous background. Magnifications up to 1000 diameters are used in observing the motion.

For a photographic record, the image of the string is projected on a slit placed parallel to the direction of motion of the image. A sensitized film behind the slit is moved at constant speed to provide a time axis. The film may be mounted on a rotating drum for short records, or fed across the slit from a reel for continuous records. An incandescent filament lamp may be used for film speeds up to 400 mm per sec at a magnification of 500 diameters. At higher speeds an arc lamp must be used.

As a rule the string is a gold-coated glass or quartz fiber about 0.001 mm in diameter, with a resistance greater than 1000 ohms. It is stretched over bridges, and its tension

is varied by a suitable slow-motion screw and lever arrangement. The string and mounting may be removed from the galvanometer as a unit. Models are available in which two or more strings can be used simultaneously with the same optical system, and in one model six strings are mounted in one optical system for simultaneous use.

Sensitivity of String Galvanometer. By changing the tension of the string the sensitivity and damping may be varied over wide limits, the sensitivity being increased by decreasing the tension with a corresponding increase in the free period. The sensitivity of a typical instrument with a 14-cm string, using a magnification of 600 diameters, is 3000 mm per μa when the string is adjusted to a period of 0.5 sec and 100 mm per μa at a period of 0.008 sec. Instruments are available with strings as short as 0.5 cm with a free period of less than 5×10^{-5} sec. Some instruments are so constructed that a number of strings of varying length can be used interchangeably, covering a wide range of sensitivity and free period.

19. TESTING OF MAGNETIC MATERIALS

MAGNETIC CHARACTERISTICS. The usual routine tests of magnetic materials consist of (1) determination of normal-induction curves and hysteresis loops, (2) determination of core loss, (3) determination of a-c permeability and core loss at low inductions, and (4) determination of the permeability of slightly magnetic materials. In commercial practice the specifications of the American Society for Testing Materials are generally followed. As these specifications are revised periodically the latest edition should be consulted.

Normal Induction. The induction produced by a given magnetizing force depends upon the previous magnetic condition of the specimen and upon the mode of approach to the given magnetizing force. In order to obtain consistent and reproducible results it is therefore necessary to follow a definite test procedure. The effect of previous magnetic history can be removed by demagnetization, that is, by subjecting the specimen to a succession of reversals of magnetizing force gradually decreasing from a certain maximum value to one somewhat lower than the lowest at which a determination is to be made. Demagnetization should be started from an initial value of magnetizing force well above that corresponding to maximum permeability, but not necessarily higher than any previously experienced by the specimen. After demagnetization, points on the induction curve are obtained by observing the induction caused by a given magnetizing force after a sufficient number of reversals to bring the material to a cyclic condition, thus closing up the hysteresis loop. After a determination has been made, further measurements can be made at higher values of magnetizing force without demagnetizing again, but if a lower point is desired, the demagnetization process must be repeated. Values of induction so obtained are called "normal induction" and are reproducible for a given specimen within the limits of experimental error. The normal-induction curve is the locus of the tips of a succession of hysteresis loops as illustrated in Fig. 45.

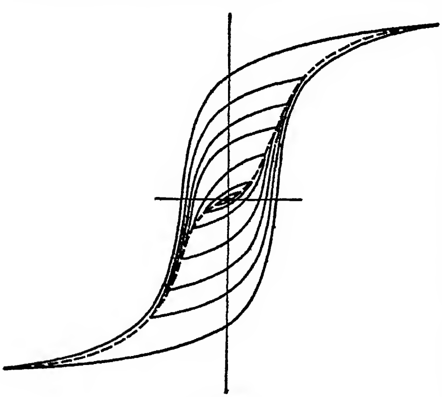

FIG. 45

Normal Hysteresis. When points on a normal hysteresis loop are to be determined, cyclic condition is first obtained by a number of reversals of the magnetizing force corresponding to the desired tip, and the induction is noted when the magnetizing force is reduced to some lower value either in the same or opposite direction. Before each determination, the material is brought back to a cyclic condition by reversals of the maximum magnetizing force. This procedure differs somewhat from the "step-by-step" method, but gives more consistent and reliable results.

MEASUREMENT OF NORMAL INDUCTION AND HYSTERESIS. CLASSIFICATION OF METHODS AND APPARATUS. Determinations of normal induction and hysteresis are ordinarily made by methods which may be classified according to the way the magnetic induction is determined, as (*a*) magnetometric, (*b*) traction, (*c*) air-gap, and (*d*) ballistic.

In the magnetometric method the induction is measured in terms of the deflection of a suspended magnetic needle placed in a definite position with respect to the test sample. The method is especially suitable for observing slow changes in induction, for instance, such as occur when a specimen is heated or cooled. The magnetometer, being very delicate and sensitive to variations in the earth's field, is not recommended for general magnetic testing.

In the traction method the induction is estimated in terms of the mechanical force of attraction between the surfaces of two magnetized bodies, one of which is the test specimen. Careful machining of the specimens is required, and the results are not of high accuracy. Traction methods are not in general use.

In the air-gap method the magnetic circuit is closed, except for a transverse air gap in which is located some measuring device, such as a deflecting coil, a rotating armature, or a bismuth spiral. The method is subject to rather large and uncertain errors.

The ballistic method employs a ballistic galvanometer (or fluxmeter) for the measurement of magnetic induction. Ballistic methods are the ones most generally used for both laboratory and shop testing. The A.S.T.M. Standards (edition of 1933) recommend for the determination of normal induction and hysteresis one of the following methods according to the type of data required and the nature of the material to be tested: (1) the ring method; (2) the Burrows permeameter; (3) the Fahy Simplex permeameter; (4) the isthmus method; (5) the Babbitt (or J) permeameter; and (6) the Simplex high-magnetization adapter.

Ring Method. The ring method is simple in principle and the easiest to apply, but it is not often used for routine testing because of the cost of preparing and winding the specimens. A diagram of connections is shown in Fig. 46. The magnetizing winding is

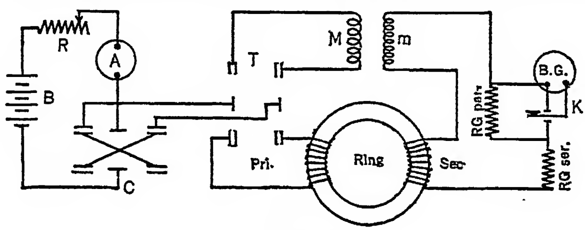

FIG. 46

uniformly distributed around the ring, and the magnetizing force in oersteds (gilberts per centimeter) is calculated from the formula

$$H = \frac{0.4\,\pi NI}{L} \tag{29}$$

in which N = total number of turns.
I = current in amperes.
L = mean circumference of ring in centimeters.

The difference in concentration of the winding over the inner and the outer part of the ring causes the magnetizing force to vary over the cross-section, with an error in the result which depends upon the ratio of the mean diameter to the radial width of the ring. If this ratio is greater than 10, however, the error can usually be neglected.

The magnetic induction is measured by the deflection of a ballistic galvanometer connected to a suitable test coil wound on the specimen, preferably under the magnetizing winding. When the flux linked with this test coil is changed, an electromotive force is induced, and a certain quantity of electricity, proportional to the change in flux, flows through the galvanometer. If the flux is reversed in direction by reversing the magnetizing current, the galvanometer deflection will be proportional to twice the flux.

The galvanometer is calibrated by means of a standard mutual inductor, the secondary of which is permanently connected in series with the test coil. It is usually convenient to adjust the sensitivity of the galvanometer by means of suitable series and parallel resistances so that the scale is direct reading in terms of magnetic induction. It is customary to make 1 cm deflection correspond to the reversal of an induction of 1000 gausses. The calibrating current to be reversed in the primary of the mutual inductor depends upon the value of the mutual inductance, the number of turns in the test coil, and the cross-section of the specimen, and is calculated from the following formula:

$$I_c = \frac{BAN}{M \times 10^8} \tag{30}$$

in which I_c = calibrating current in amperes.
B = induction in gausses.
A = cross-sectional area in square centimeters.
N = number of turns in the test coil.
M = mutual inductance in henrys.

It is often convenient to use 100 turns in the test coil. When points on the hysteresis loop are to be determined, an auxiliary series resistance is suddenly inserted in the magnetizing circuit. In this case, since the galvanometer is calibrated for reversal of the induction, the readings must be multiplied by 2.

Burrows Permeameter. It is generally most convenient to prepare samples in the form of straight bars of moderate length and uniform cross-section. Of the various testing methods adapted to such samples the most accurate one, for samples of uniform permeability along their length and having a maximum permeability not exceeding 5000, is the Burrows compensated double-yoke method. In this method auxiliary compensating coils provide the extra magnetomotive force required for the yoke and joints in the magnetic circuit, the current in them being adjusted so as to produce a uniform induction in the test bar. Fig. 47 shows the magnetic circuit of the Burrows permeameter and the relative positions of the magnetizing and the test coils. The test rod and its auxiliary, which should be of the same size and material, are joined at the ends by soft-iron yokes which make good magnetic joints. The magnetizing coils T and A are located over the test rod and auxiliary, respectively. Coil J is in four sections, connected in series, and located over the ends of the rods as near to the joints as possible. In operation, the currents in these three windings are so adjusted before each reading that there is equal flux in the two rods, and no leakage from the greater part of the test rod; for this

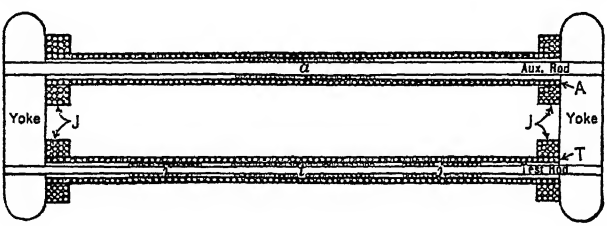

FIG. 47

condition, the value of the applied magnetizing force can be calculated from the current and number of turns per centimeter in the solenoid surrounding the test rod. For testing the compensation and determining the value of the induction when the compensation is properly adjusted there are three test coils designated as t, a, and j, respectively. These coils are each of the same number of turns and are distributed as shown in the figure; t is wound over the middle of the test bar, a over the middle of the auxiliary bar, and j half over one end and half over the other end of the test bar far enough away from the yokes and joints to avoid disturbances from these causes. When the reversal of the magnetizing currents causes no deflection of the galvanometer whether connected to t and a or to t and j in series-opposition, the magnetizing currents are properly adjusted, the induction may be measured in terms of the deflection of the galvanometer connected to t alone, and the magnetizing force is proportional to the current in the winding T. As usually constructed, the magnetizing coil is so wound that the magnetizing force is 100 times the current in amperes. A diagram of connections is given in Fig. 48. The switches ST, SA, and SJ serve to insert resistances in the corresponding circuits during the determination of points on the hysteresis loop. ST should make contact on the forward point before breaking at the other. The calibration of the ballistic galvanometer is carried out as indicated for the ring method.

In all ballistic methods a correction must be made to the observed value of induction because of the flux in the space between the specimen and the test coil. The amount to be subtracted from the observed value of induction is proportional to the magnetizing force H and depends upon the relative areas of the test coil and specimen. It is equal to kH where

$$k = \frac{a - A}{A}$$

a = area of test coil
A = area of specimen

This "air correction" may be eliminated by means of an adjustable mutual inductor having its primary in series with the main magnetizing winding and its secondary in series with the main test coil. If desired, the two main magnetizing coils may be connected in series and the average values for the two samples determined by connecting the two middle test coils in series and using them as one. In this arrangement, four auxiliary test coils near the ends of the specimens are connected in series and used as one coil for adjusting the current in the compensating magnetizing coils.

The Burrows permeameter is an absolute instrument in that its constants can be derived from measurements of its dimensions, and it is therefore suitable for standardization work under proper conditions. It is extremely sensitive to variations in permeability along the length of the specimen, and the results obtained on inhomogeneous material should be interpreted with this fact in mind.

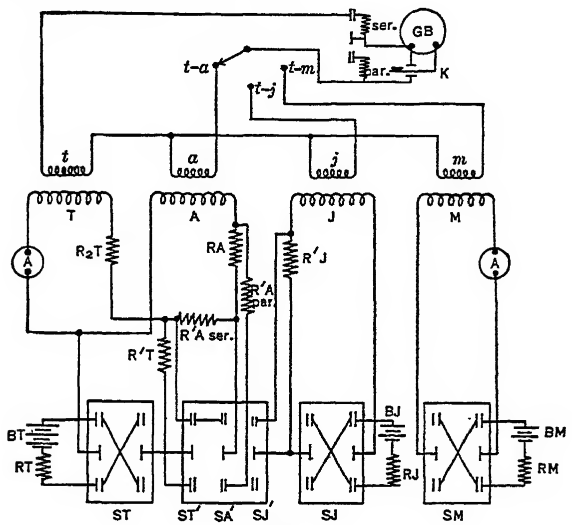

FIG. 48

Fahy Simplex Permeameter. This permeameter requires but a single specimen. The magnetizing force is applied by means of an electromagnet, across the poles of which the specimen is clamped. A uniformly wound test coil extends over the whole length of the specimen. A ballistic galvanometer connected to this test coil indicates the induction in the specimen when the magnetizing current is reversed. The magnetizing force is measured by means of a test coil uniformly wound on a non-magnetic form and extending between two iron blocks which are clamped to the ends of the specimen.

When the magnetizing force is changed in value, the deflection of a ballistic galvanometer connected to this coil is proportional to the change in magnetic potential between the ends of the coil. The function of the iron blocks is in effect to transfer the ends of the test coil to the ends of the specimen. When the magnetic circuit is properly constructed of suitable materials, this method is capable of giving very satisfactory results. It does not require an auxiliary specimen, and no compensation is necessary. It is also less sensitive than the Burrows permeameter to the effect of magnetic inhomogeneity along the length of the specimen. The galvanometer is calibrated by means of a standard mutual inductor as in the methods described above, and the correction for air-flux linked with the test coil but not in the specimen is applied.

Isthmus Method. The isthmus method was developed originally for the measurement of saturation values of intrinsic induction. It is based on the theory that the magnetizing force just outside the surface of a specimen is equal to that within. Two modifications of this method have been developed at the Bureau of Standards. The first modification is suitable for tests within the range from 100 to 3000 oersteds. It employs an electromagnet with its pole pieces pierced coaxially to receive a specimen 6 mm in diameter. The du Bois form of electromagnet has been found most convenient. The gap between the pole pieces is 2 cm long. Surrounding the specimen are two con-

centric and coextensive test coils each having the same number of turns. The inner coil is of as small diameter as possible (about 7 mm); the outer coil has a diameter of approximately 12.5 mm. It is essential that the proper dimensions of specimen, gap, and test coils be used in order to ensure uniformity of the magnetizing force throughout the space occupied by the test coils. Normal-induction measurements are made upon reversal of the magnetizing current. When the galvanometer is connected to the two coils in series-opposition, the deflection upon reversal is proportional to the magnetizing force. When the galvanometer is connected to the inner coil alone, the deflection upon reversal is proportional to the induction in the specimen. Special switching arrangements are required for the determination of points on the hysteresis loop.

Since it is often inconvenient to prepare specimens 6 mm in diameter, a second modification of the isthmus method has been developed to accommodate test specimens of rectangular cross-section. The range of this apparatus is from 100 to 1000 oersteds. The test specimens are clamped in pole pieces between two similar U-shaped yokes of laminated silicon steel upon which the magnetizing coils are wound. The length of the gap and the dimensions of the test coils are so chosen that the magnetizing force throughout the space occupied by the test coils is substantially uniform. The coil surrounding the specimen for the measurement of induction is sufficiently large to accommodate the largest specimen for which the apparatus is adapted. In order to obviate the necessity for making a large air-flux correction a compensating coil having the same value of area-turns is connected in series-opposition. The compensating coil and the test coil for the measurement of magnetizing force are wound on a common form located within the uniform part of the field between the pole pieces.

Babbitt (or J) Permeameter. This permeameter is designed especially for testing in the range 40 to 1000 oersteds. The specimen is clamped between the poles of a laminated yoke made up of different kinds of material such as permalloy, silicon steel, and ordinary iron in such proportions that the resultant permeability is practically constant throughout the range of flux density carried by the yoke. Compensation for the yoke reluctance is effected by a winding surrounding the yoke and connected in series with the main magnetizing winding around the test specimen. The value of induction is determined ballistically by means of a test coil surrounding the specimen. The air correction is eliminated by means of an auxiliary test coil placed within the magnetizing coil but not surrounding the specimen. The area-turns of this auxiliary coil are adjusted to equal the area-turns of the main test coil to which it is connected in series-opposition. The readings thus give values of intrinsic induction ($B - H$). The value of magnetizing force is determined either in terms of the magnetizing current (using an experimentally determined constant) or by means of an air coil mounted within the magnetizing solenoid. Care must be exercised in the use of this instrument to avoid excessive heating of the specimen.

Simplex High-Magnetization Adapter. This is an attachment to be used with the Fahy Simplex permeameter. By its use the span of the instrument is reduced to 1.25 in. Test coils similar to those used with the regular instrument, but shorter, serve for the determination of induction and magnetizing force. According to the A.S.T.M. specifications, this apparatus can be used for the determination of maximum induction, B_m, residual induction, B_r, and coercive force H_c, of materials having high coercive force with the reservation that the observed values of coercive force may be low by from 0 to 10 or 12 per cent, the error generally increasing with the thickness of the specimen.

NOTE. At the 1935 meeting of the A.S.T.M. two additional instruments were tentatively approved for tests at magnetizing forces in the range of 100 to 2500 oersteds, namely the Simplex Super-H Adapter and the Saturation Permeameter.

GENERAL PRECAUTIONS. In magnetic testing the following precautions should be observed: (1) in order to obtain consistent and reproducible results, the specimen (and yoke) must be thoroughly demagnetized before the measurements are made; (2) stray fields, especially from parts of the electrical circuit in which current changes during an observation, should be avoided (this can generally be accomplished by twisting together the current-carrying conductors and also the secondary circuits); (3) specimens should be clamped so as to be free from mechanical strain; (4) heating of the specimen should be avoided; (5) specimens should be protected from mechanical vibration.

ACCURACY OF MAGNETIC TESTS. The most common sources of error in magnetic testing are (1) lack of uniformity in permeability along the length of the specimen; (2) mechanical strain; and (3) temperature effects. Errors due to these causes may be large and cannot be estimated with any degree of certainty. The methods mentioned above may be expected to give the following accuracies for specimens having a satisfactory degree of uniformity, clamped so as to be free from strain and kept at a constant temperature within 5 deg cent: For normal induction up to the point of maximum permeability,

values of magnetizing force corresponding to given values of induction should be accurate within 3 per cent provided that the permeability does not exceed 10,000. This limitation as to permeability does not apply to the ring method. Values of induction corresponding to given values of magnetizing forces above the point of maximum permeability should be accurate within 1 per cent. For residual induction, values should be accurate within 2 per cent and for coercive force within 5 per cent, except in the case of the Simplex Adapter as noted above. For magnetically inhomogeneous material the accuracies specified above cannot be obtained with the Burrows permeameter. The Fahy Simplex permeameter and the Babbitt permeameter, each used within its proper range, give values more nearly representative of the average properties of non-uniform material. Unless a specimen has been tested for uniformity, it is usually safe to assume that it is non-uniform.

TESTING MATERIALS OF LOW PERMEABILITY. GENERAL LABORATORY METHOD. The methods described above are not adapted to the testing of materials of very low permeability. The commercial importance of such tests lies in the relationship that has been found between the magnetic permeability and the resistance to corrosion of certain types of corrosion-resistant steel. The permeability of such materials ranges from about 1.01 to about 5.0. A ballistic method is generally employed. A straight solenoid is used which has a test coil of several hundred turns mounted within it, and in which the specimen can be inserted. Because of the very low value of magnetization in the specimen, the self-demagnetizing effect is so small that it can be neglected. A variable mutual inductor is used, with its primary connected in series with the magnetizing solenoid and its secondary in series-opposition with the test coil. This mutual inductor is so adjusted as to balance the mutual inductance between the solenoid and the test coil. This adjustment is made with no specimen in the test coil, so that there is no deflection of the ballistic galvanometer when the primary current is reversed. The galvanometer can then be used at its maximum sensitivity. When a specimen is inserted within the test coil and the magnetizing current is reversed, the deflection of the galvanometer is proportional to the intrinsic induction of the specimen. The magnetizing force is calculated from the current and the constants of the solenoid in the usual way.

The Fahy Low-Mu Permeameter. This instrument is a modification of the one described above. The variable mutual inductor is replaced by an air coil mounted within the magnetizing solenoid and adjacent to the test coil. The value of area-turns of this air coil is slightly greater than that of the test coil. The value of effective area-turns of the air coil is adjusted by means of a variable resistance connected in parallel with the coil. The adjustment of the shunt resistance is correct when the galvanometer connected to the two secondary coils is not deflected upon reversal of the magnetizing current. The deflection obtained upon reversal with a specimen inserted in the test coil is proportional to the intrinsic induction ($B - H$). The magnetizing force is measured by means of the auxiliary coil with the shunt resistance disconnected. Calibration is carried out with a standard mutual inductor in the usual way as described under the ring method.

Measurement of Core Loss

The use of the wattmeter method for the measurement of core loss is now almost universal. Large quantities of electrical sheet are purchased annually on specifications as to their core-loss values. In the interest of uniformity, producers and consumers of this type of material have standardized on the Epstein method as specified by the American Society for Testing Materials.

A.S.T.M. 1933 STANDARD CORE-LOSS TESTS. Test Specimens. Test specimens shall consist of 10 kg (22 lb) of strips 50 cm (19 $^{11}/_{16}$ in.) in length and 3 cm (1 $^{3}/_{16}$ in.) in width cut with sharp shears from two or more sheets taken at random from shipment. One-half of the strips shall be cut parallel to the direction of rolling, and the other half at right angles to this direction. (See Note 3.) It is recommended that a test specimen shall represent not more than 5000 kg (11,000 lb). The strips shall be cut symmetrically from the sheet as nearly as may be practicable.

Place on the balance a pile of test strips weighing 2.5 kg. Add a second pile of the same kind, bringing the weight up to 5 kg. In each case the weight shall be taken to the nearest strip. Add in succession two piles of 2.5 kg each, of the other kind of strips, bringing the weight up to 7.5 kg and 10 kg, respectively. Care should be taken to keep separate the strips which are cut at different directions of the grain.

NOTE. If desired, for convenience, the bundles may be loosely secured by tape or string (not wire).

NOTE 2. If desired, a 5-kg specimen may be used for routine acceptance tests, provided it is cut from at least two sheets, except in case of a dispute between the manufacturer and the purchaser, when the 10-kg specimen shall be used.

NOTE 3 (Adopted by A.S.T.M., 1935). When the material is to be used with the flux in any one direction with respect to the direction of rolling or has preferred properties in any one direction with respect to the direction of rolling, strips may be cut in a specified direction if there is mutual agreement between manufacturer and purchaser. It must always be specifically stated when tests are so made. Only one type of strip will than be necessary for such tests.

Apparatus (Epstein). The magnetizing winding shall consist of four solenoids surrounding the four sides of the magnetic circuit and joined in series. A secondary coil shall be used for energizing the voltmeter and the voltage coil of the wattmeter.

These solenoids shall be wound on a form of any non-magnetic, non-conducting material of the following dimensions: inside cross-section, 4 by 4 cm; thickness of wall, not over 0.3 cm; winding length, 42 cm. The primary winding on each solenoid shall consist of 150 turns of copper wire uniformly wound over the 42-cm length. The total resistance of the magnetizing winding shall be between 0.3 and 0.5 ohm. The secondary winding of 150 turns of copper wire on each solenoid shall be similarly wound beneath the primary winding. Its resistance shall not exceed 1 ohm.

A voltmeter and the voltage coil of a wattmeter shall be connected in parallel to the terminals of the secondary winding of the apparatus. The current coil of the wattmeter shall be connected in series with the primary winding. A low-power-factor wattmeter shall be used.

Test Procedure. The standard core loss shall be measured under the following conditions: The magnetic circuit shall consist of 10 kg (22 lb) of the test material, one-half parallel and one-half at right angles to the direction of rolling, made up into four equal bundles, two containing material parallel and two containing material at right angles to the direction of rolling, and finally built into the four sides of a square with butt joints and opposite sides consisting of material cut in the same manner. No insulation other than the natural scale of the material (except in the case of scale-free material) shall be used between laminations, but the corner joints may be separated by tough paper approximately 0.1 mm (0.004 in.) in thickness.

An electromotive force having a wave form approximating a sine curve shall be applied to the primary winding and adjusted until the voltage of the secondary circuit is that determined by the equation.

$$E = \frac{4ff\,NfBM}{4lD10^5} \tag{31}$$

where ff = form factor of primary emf = 1.11 for sine wave.
N = number of secondary turns = 600.
f = number of cycles per second = 60.
B = maximum induction in kilogausses = 10 kilogausses.
M = total mass in grams = 10,000 grams.
l = length of strips in centimeters = 50 cm.
D = density in grams per cubic centimeter, = 7.5 grams per cm^3 for high-resistivity steel, 7.7 grams per cm^3 for low-resistivity steel.
E = 106.6 volts for high-resistivity steel for sine voltage, 103.8 volts for low-resistivity steel for sine voltage.

NOTE. For the 14-kilogauss test the voltages will be as follows: E = 149.2 volts for high-resistivity steel for sine voltage, 145.2 volts for low-resistivity steel for sine voltage.

The form factor of the applied electromotive force shall not vary more than 1 per cent from the value of 1.11. If desired, an average-value voltmeter can be substituted for or used in conjunction with the rms voltmeter.

NOTE. See G. Camilli, A flux voltmeter for magnetic tests, *J. A. I. E. E.*, 1926, vol. 45, p. 989; also B. M. Smith and C. Concordia, Measuring core loss at high densities, *Elec. Eng.*, 1932, vol. 51, p. 36.

As an alternative to the use of a sine wave, the correct value of a non-sinusoidal voltage may be determined by applying it to an Epstein apparatus containing a sample of similar material which has been standardized by means of a sine-wave electromotive force. The wattmeter is brought to the correct reading for the standard sample. The corresponding voltage is the correct one to use. This alternative method may be modified by comparing standard and test samples by means of a differential wattmeter. For this test, the secondary voltage needs to be only approximately correct. When using these comparison methods, the form factor of the induced voltage wave should not differ from 1.11 by more than 5 per cent.

For silicon steels, a density of 7.7 grams per cm^3 shall be assumed if the silicon content is 2 per cent or less and a density of 7.5 grams per cm^3 shall be assumed if the silicon content is above 2 per cent.

For nickel-iron alloys the density shall be assumed from the nickel content as given by the straight lines joining the points defined as follows:*

Nickel, per cent	Density, grams per cm^3
0	7.85
30	8.00
100	8.90

For other alloys a density corresponding to the actual measured or estimated value shall be used.

Apply the alternating voltage to the primary coil and tap the joints together until the current has a minimum value, as shown by an ammeter in series. Then clamp the corners firmly by some suitable device.

Shunt the ammeter and adjust the primary current until the voltmeter indicates the proper value. This adjustment may be made by an auto-transformer, by varying the field of the alternator, or by both, but not by the insertion of resistance or inductance in the primary circuit. Simultaneously, the frequency shall be adjusted to 60 cycles.

Read the wattmeter when the voltage and frequency are correct. The wattmeter gives the power consumed in the iron and the secondary circuit. The loss in the secondary circuit is given in terms of the total resistance and voltage. This loss $= E^2/R$ where E is the secondary rms voltage and R is the parallel resistance of the voltmeter and the shunt circuit of the wattmeter. Subtract from the wattmeter reading the loss in the secondary circuit, which will be constant for any set of instruments and voltage, and divide by the weight of the sample in kilograms. The result is the standard core loss.

NECESSITY FOR A-C PERMEABILITY AND CORE-LOSS DATA AT LOW INDUCTIONS. In current transformers, and in many forms of apparatus used in communication, magnetic core material is run at very low values of flux density ranging from 10 gausses (or less) to 1000 gausses. The ordinary testing methods are not suitable for testing at such low inductions. The A.S.T.M. specifications describing two methods suitable for testing at low inductions are as follows:

A.S.T.M. 1933 STANDARD TESTS AT LOW INDUCTIONS. Scope. These methods provide for the determination of the a-c permeability and core loss of magnetic materials at low inductions. These properties are indicative of the effect of the material on the impedance and loss characteristics of apparatus in which the core materials are worked at low inductions.

Standard Values. Tests shall be made either at a frequency of 60 cycles per second or at 1000 cycles per second. Standard values at 60 cycles per second are those corresponding to a maximum induction of 10 gausses or 1000 gausses, according to the use for which the material is intended. At 1000 cycles per second, the standard values are those corresponding to a maximum induction of 10 gausses.

NOTE. Apparatus often operates under conditions in which the alternating magnetization is superposed upon a steady unidirectional magnetization, but it is not necessary to introduce this complication into the standard tests, as the relative quality of materials is adequately indicated by the simple a-c tests.

Test Specimens. Test specimens shall consist of not less than 1 kg (2.2 lb) of the test material cut with sharp shears into strips 25 cm (9 27/32 in.) in length and 3 cm (1 3/16 in.) in width, one-half parallel and one-half at right angles to the direction of rolling, made up into four equal groups, two containing material parallel and two containing material at right angles to the direction of rolling. The four groups shall then be assembled in the test coils to form a square with the corners so arranged that the layers alternately butt and lap. The opposite sides of the square shall consist of material cut in the same manner. When testing for core loss, the separate laminations shall be effectively insulated from one another.

The tests may be made either by the bridge method or by the a-c potentiometer method, both of which are specified below.

Power Supply. The supply voltage shall be of approximately sine-wave form, having not more than 10 per cent of total harmonics present.

Test Winding. The test winding shall consist of four solenoids surrounding the four sides of the magnetic circuit and connected in series. These solenoids shall be wound on forms of any non-magnetic, non-conducting material of the following dimensions: inside cross-section, 3.2 by 1 cm; thickness of wall, not over 0.3 cm; winding length,

* For 50 per cent nickel content the density is 8.26 grams per cm^3. For 80 per cent nickel content the density is 8.64 grams per cm^3

17 cm. There shall be two windings on each solenoid. The inside winding shall consist of 25 turns of insulated copper wire uniformly wound over the 17-cm length, and the total series resistance of the four coils shall not exceed 0.05 ohm. The second winding shall consist of 250 turns per solenoid uniformly wound over the first, and the total series resistance shall not exceed 2 ohms.

Apparatus for Bridge Method. The apparatus shall consist of the following (see Fig. 49): Any voltmeter capable of indicating the voltage supplied to the bridge at the test frequency with an accuracy of at least ±2 per cent may be used. A voltmeter of the multi-range vacuum-thermocouple type is recommended. The **fixed condenser,** C_3, shall be a high-grade mica condenser having a capacitance of 1.0 μf ±0.25 per cent, and a power factor of not more than 0.0015 at 1000 cycles per second. The **adjustable condenser,** C_4, shall be a three-decade condenser having steps of $9 \times (0.1 + 0.01 + 0.001)$ μf adjusted to an accuracy of ±(0.25 per cent + 50 $\mu\mu f$), and having a power factor of not more than 0.0015 at 1000 cycles per second. In addition, C_4 shall include a single 1-μf mica condenser of the same accuracy, with suitable means for inserting it in the circuit. The **fixed resistor,** R_1, shall be a non-reactive resistor of 10 ohms ±0.1 per cent, with a time constant not to exceed 1 microsecond, or a 100-ohm resistor of the same percentage accuracy. (Time constant is defined as the inductance in henrys divided by the resistance in ohms, or the shunt capacitance in farads multiplied by the resistance in ohms.) The **adjustable resistor,** R_4, shall be a four-decade non-reactive resistor having steps of $10 \times (1{,}000 + 100 + 10 + 1)$ ohms adjusted to an accuracy of ±(0.1 per cent +0.05 ohm) with a time constant not to exceed 1 microsecond. Any **zero-current detector** having the necessary sensitivity may be used. For the 60-cycle test, a vibration galvanometer is recommended; for the 1000-cycle test a telephone receiver is recommended. A single-stage vacuum-tube amplifier preceding the galvanometer or receiver is recommended when it is necessary to increase the sensitivity. The **supply transformer,** T, shall be a suitable transformer providing efficient and distortionless inductive coupling and substantial electrostatic isolation between the source of supply and the bridge network.

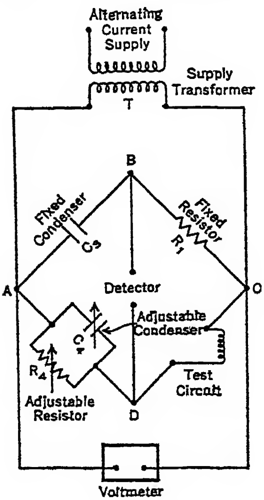

FIG. 49

Procedure for Bridge Method. For the 60-cycle test on exceptionally high-permeability low-loss material, such as hipernik or permalloy, use the 25-turn windings and $R_1 = 10$ ohms. For silicon steel, and materials of similar magnetic properties, use the 250-turn windings and $R_1 = 100$ ohms. For the 1000-cycle test use the 25-turn windings and $R_1 = 10$ ohms for both classes of material. The test specimen shall be thoroughly demagnetized before testing.

Set the voltage, E, to give the desired induction in accordance with the relation

$$E = 0.0707AB \tag{32}$$

where B = the maximum induction in gausses.

A = the cross-sectional area of the specimen in square centimeters, calculated from values of length, mass, and density. Values of density either may be assumed as indicated on p. 78, or may be experimentally determined.

Adjust R_4 and C_4 to balance the bridge. Then

$$\mu = \frac{0.795R_4}{A}\cdot\frac{R_1}{N^2}\cdot 10^4 \tag{33}$$

For $N = 100$ and $R_1 = 10$

$$\mu = \frac{7.95R_4}{A} \tag{34}$$

For $N = 1000$ and $R_1 = 100$

$$\mu = \frac{0.795R_4}{A} \tag{35}$$

and the loss

$$P = E^2\left[C_4\omega^2(C_3R_1) - R_{dc}\left(\frac{1}{R_4^2} + C_4^2\omega^2\right)\right] \tag{36}$$

where P = the total loss in watts.
A = the cross-section in square centimeters.
C_4 = the value of adjustable condenser in farads.
ω = 2π times the frequency in cycles per second.
N = the number of turns.
R_{dc} = the resistance of winding in ohms.
R_4 = the value of adjustable resistance in ohms.

NOTE. P divided by the mass in kilograms gives the loss in watts per kilogram.

Apparatus for Potentiometer Method. The apparatus shall consist of the following (see Fig. 50): The a-c potentiometer shall be of the coordinate type, indicating voltage in terms of two components having a quadrature phase relation. A suitable phase-shifting device shall be provided to adjust the phase of either the potentiometer supply or the magnetizing current. The resistor, R, shall be a non-inductive resistor of such a resistance as to give a potential drop of suitable magnitude. The resistances should be adjusted to an accuracy of ±0.1 per cent, with a time constant not to exceed 1 microsecond.

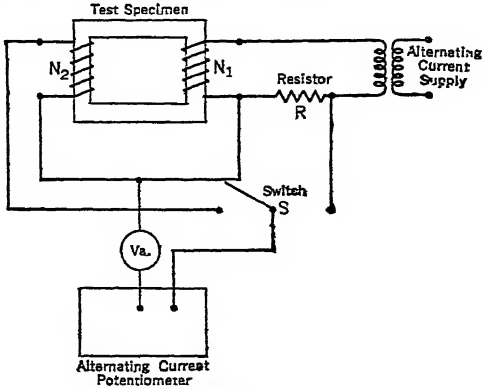

FIG. 50

Procedure for Potentiometer Method. Use the 100-turn winding for the primary and the 1000-turn winding for the secondary, unless the secondary voltage exceeds the range of the potentiometer. Under these conditions, which may occur for the 1000-gauss test, the two windings may be interchanged. The test specimen shall be thoroughly demagnetized before testing.

Throw the switch, S (Fig. 50), so as to connect the potentiometer to the secondary winding and adjust the phase so that the total voltage is read on the in-phase dial, the quadrature dial being set to zero. Set the voltage E to give the desired induction in accordance with the relation:

$$B = \sqrt{2}\pi f N_2 AB \times 10^{-8} \tag{37}$$

where the symbols have the same significance as in the bridge method; f = frequency in cycles per second; and N_2 = number of secondary turns.

Throw switch S to connect the potentiometer to the resistor, R, and read the voltage. The power component is then indicated by the in-phase voltage, and the magnetizing component is indicated by the quadrature voltage. The corresponding values of current are obtained by dividing the voltage by the resistance, R. Denoting the in-phase and quadrature currents by I_P and I_Q, respectively:

$$\mu = 56.3 \frac{B}{N_1 I_Q} \tag{38}$$

and

$$P = \frac{N_1}{N_2} E I_P \tag{39}$$

where the symbols have the same significance as above, and N_1 = number of primary turns. P divided by the mass in kilograms gives the loss in watts per kilogram.

20. TESTING OF INSULATING MATERIALS

The most important electrical properties of an insulating material are its dielectric strength, resistivity, dielectric constant, and dielectric loss. Some of the common methods of measuring these quantities are described below.

Measurement of Dielectric Strength

The dielectric strength of an insulating material is defined as the puncturing voltage per unit thickness, the thickness being measured either in centimeters or in mils (1 mil = 0.001 in.). The voltage required is in general higher than can be conveniently obtained from d-c sources of emf, and alternating emf's are therefore used in such tests.

The materials to be tested are placed between electrodes connected to the high-voltage terminals of a transformer which receives power from a low-voltage alternator.

TRANSFORMERS AND ALTERNATORS FOR DIELECTRIC TESTING. For making routine tests of dielectric strength, any well-designed high-voltage transformer connected to a suitable a-c supply may be used. For the purpose of comparison and computation of the maximum emf from the effective value, it is essential that the high-voltage transformer deliver as nearly a pure sine-wave voltage as possible. Both transformer and alternator should be large enough to operate with good voltage regulation at all testing loads, so that no serious distortion of the wave form will be produced by the charging current. The transformer and source of supply should have a rating of at least 2 kva for voltages under 50,000 volts, and at least 5 kva for voltages above 50,000 volts. For ordinary tests the frequency should not exceed 100 cycles per second.

Special tests, or tests calling for extremely high voltages or frequencies, will require special equipment.

CONTROL OF VOLTAGE. The method of voltage control should be such that the high voltage from the secondary of the testing transformer can be raised gradually from any point. In no case should the control of voltage be by discontinuous steps of more than 500 volts each. The control may be effected by means of generator field regulation, an induction regulator, a variable-ratio auto-transformer, or a combination of these methods. By using a variable-ratio auto-transformer and varying the field excitation of the alternator, the variation of field saturation in the alternator may be reduced to a minimum and the shape of the voltage wave kept almost constant over a wide range of secondary voltage. Any method of regulating the voltage may be considered satisfactory for ordinary work which does not distort the wave more than 10 per cent from a sinusoidal shape.

MEASUREMENT OF VOLTAGE. The voltage impressed upon the material under test may be determined by an adjustable spark gap shunted across the electrodes, a voltmeter and multiplier connected across the electrodes, an electrostatic voltmeter connected across the electrodes, a voltmeter connected across the low-voltage terminals of the transformer, the readings of which are to be multiplied by the step-up ratio of transformation, a voltage transformer with a voltmeter connected across its low-voltage terminals, or a special voltmeter winding placed in the middle of the high-voltage windings of the step-up transformer. The needle-spark-gap method, though convenient because of its indication of the maximum rather than the effective value of the voltage, is tedious in use, its readings are dependent upon the circulation of air, the condition of the needles, the proximity of neighboring objects, etc. The sphere spark gap is preferable; see Spark Gaps for Measuring High Voltages. The use of the voltmeter and multiplier, though flexible and convenient, is not recommended because of the load which is placed upon the transformer and the possibility of leakage in the multiplier. The use of an electrostatic voltmeter is desirable, except that at high voltages the moving element must be immersed in oil, making the instrument sluggish in action. The instrument is also liable to breakdown. In any method involving the ratio of transformation of the transformer, results which are based on the assumption that this ratio is constant are questionable.

The most satisfactory and accurate measurements of voltage are obtained, as a rule, with the separate step-down voltage transformer and voltmeter, or with a voltmeter connected to a special voltmeter coil in the testing transformer.

PROTECTION OF APPARATUS. Some protection of the measuring apparatus is necessary when using voltages such as are commonly employed in making breakdown tests. A circuit breaker should be provided in the low-voltage side of the test transformer to prevent damage to the transformer or alternator when the specimen breaks down. In addition, some protection is needed in the high-voltage circuit of the test transformer, when the voltage is 25,000 volts or over, to prevent dangerous surges of current in this circuit when the specimen punctures. It is desirable, however, to have as much energy available as possible when the puncture occurs. If impedance in the form of choke coils is used in series with the high-voltage terminals, it should not be greater than that which will limit the high-voltage current to double the normal rated current of the transformer. See Precautions in Use of Sphere Gap.

FORMS OF ELECTRODES. The breakdown voltage of a specimen depends to a marked extent upon the size and shape of the electrodes used and the nature of the surrounding medium. Inge and Walther (see Bibliography) have made extensive experimental investigations of the effects of these and other variables upon the breakdown voltage of various substances. If the edges of the electrodes used are not rounded, the increased flux density at the edges produces an excessive stress on the dielectric, and failure of the specimen almost invariably occurs at these points. At higher voltages, say over a few thousand volts, some means must always be provided to prevent corona and flash-

over at the edges of the electrodes; otherwise the resultant heating of the specimen would entirely vitiate the results.

The American Society for Testing Materials recommends that the electrodes for testing sheet materials be 2-in. cylinders, 1 in. in length, with edges rounded to a radius of $^1/_4$ in. For oils, the electrodes recommended are circular disks of polished copper or brass 1 in. in diameter and having square edges. The oil electrodes are mounted in a test cup with their axes horizontal and coincident, with a gap of 0.1 in. between their adjacent faces. By far the most complete single summary of current practice with respect to testing electrical insulating materials will be found in the specifications of this Society (see Bibliography).

METHOD OF APPLYING VOLTAGE. Materials may be tested by impressing the puncturing voltage, (1) instantaneously; (2) as a continuously increasing voltage, at a specified rate, beginning with an initial low voltage; (3) in steps of a specified value held for a given duration of time. The method of application of voltage is a significant factor in the comparison of breakdown voltages. It is customary to use method (2), with a rate of increase of voltage of approximately 1000 volts per second, or method (3), with steps of 500 volts applied for 1 minute each. Procedure with respect to these last two points is not as yet completely standardized.

CAUSES OF VARIATIONS IN RESULTS. The puncturing voltage of an insulating material is affected by its previous history, its precise condition when tested, its size and thickness, its temperature, the nature of the electric field to which it is subjected, the frequency of the applied voltage, and the method by which the puncturing voltage is applied. For crystalline materials such as mica the puncturing voltage (expressed as volts per centimeter or volts per mil) is independent of temperature and increases with decreasing thickness of the specimen. For fibrous and synthetic materials the puncturing voltage is probably affected more by temperature than by any other factor. In any case it is necessary to prevent corona discharge and flashover at the edges of the electrodes. This is commonly accomplished by immersing the specimen in oil. The nature of the electric field to which the specimen is subjected is largely determined by the size of the specimen, the size and shape of the electrodes used, and the nature of the surrounding medium. Results of dielectric-strength tests are not immediately comparable unless obtained under strictly comparable experimental conditions.

Measurement of Insulation Resistance

The method commonly used is one of substitution, that is, the deflection of a galvanometer is noted when a standard resistance R_s (0.1 or 1 megohm as the case may be) is inserted in series with the galvanometer and a source of emf and again when the unknown resistance R_x is inserted in the same circuit. A galvanometer should be used the sensitivity of which is such as to give deflections of the order of 1 mm at a scale distance of 1 meter, for a current of 10^{-9} amp. The deflections of the galvanometer should be proportional to the current. The galvanometer should be provided with an Ayrton-Mather universal shunt (see Galvanometer Shunts) such that the current under measurement will be a known multiple, K, of the galvanometer current. The shunt factor K may be 10, 100, etc. Voltages from 100 to 500 volts may be used in determining the unknown insulation resistance. Because of the difficulty of producing and maintaining resistance standards of extremely high values it will generally be necessary not only to decrease the sensitivity of the galvanometer, but also to decrease the voltage used when calibrating the galvanometer with the standard resistance, in order to keep the galvanometer deflection within the scale limits.

The test is made by observing the shunt factor, the voltage, and the galvanometer deflection when the standard resistance is inserted in the circuit and again when the unknown is inserted. The unknown resistance is then calculated from the equation,

$$R_x = R_s \frac{K_s E_x D_s}{K_x E_s D_x} \tag{40}$$

where, when measuring the specimen, K_x is the shunt factor, E_x the applied voltage, and D_x the galvanometer deflection; K_s, E_s, and D_s represent the corresponding quantities when employing the standard resistance, and R_s represents the value of the standard resistance. With such an arrangement resistances of 10^4 to 10^{11} ohms can be measured, the accuracy being of the order of 10 per cent.

Where the resistance is too high to make the deflection method feasible, the leakage current through the specimen is allowed to charge a condenser for a known interval. The condenser is then discharged through the galvanometer. Then

$$R_x = \frac{Et}{KD} \tag{41}$$

where E is the applied voltage, t the time of charge, K the ballistic constant, and D the deflection. By this method resistances from 10^{11} to 10^{15} ohms can be measured.

Resistances from 10^{15} to 10^{17} ohms can be measured if a quadrant electrometer is used to measure the current through the unknown resistance. The equation for R_x is identical in form with that given above for the ballistic-galvanometer method; E is the applied voltage, t is the time required to produce a deflection V, and K is the quantity of electricity necessary to produce unit deflection. By this method R_x can be determined at any instant.

The **volume resistivity** of a material is defined as the resistance to the current flowing through the material between two opposite faces of a centimeter cube. The **surface resistivity** of a material is defined as the resistance to the current flowing between opposite edges of a surface film which is 1 cm square. When results are to be expressed in terms of volume resistivity or of surface resistivity it is necessary to use electrodes of known dimensions, in good contact with the specimen. Metallic electrodes, wrapped in tin foil and carefully pressed against the specimen, may be used. Where the nature of the specimen permits, the specimen may be floated on a pool of mercury with an upper electrode of mercury contained within a suitable dam. Great care must be taken to provide suitable guard rings in making such measurements, for a discussion of which see paper by H. L. Curtis, Insulating properties of solid dielectrics, *Bull. Bur. Standards*, 1915, vol. 11, p. 359; reprinted as Bur. Standards Sci. Paper 234. In any case it is essential to note the temperature of the material, the relative humidity, the voltage used, and the time of application of the voltage. Since these resistance values in general vary with time after the application of voltage, it has become customary to take the resistance 1 minute after the application. Since surface resistivity is largely a surface-film phenomen, the past history of the sample, such as exposure to sunlight, moisture, corrosive vapors, etc., will materially affect its value.

Self-contained instruments are available for measuring insulation resistance (see Ohmmeters).

Measurement of Dielectric Constant, Dielectric Loss, and Power Factor

The dielectric constant of any substance is defined as the ratio of the capacitance of a condenser in which the substance in question fills the space between the plates to the capacitance of the same condenser in vacuum, that is, to the geometric capacitance of the condenser. This ratio, designated by K, may vary with the temperature of the substance, the time after the application of voltage to the dielectric, and therefore with the frequency when tested with alternating voltages. The dielectric constant of most substances decreases as the temperature increases. The dielectric constant in general increases with time after the application of voltage and hence decreases as the frequency increases.

The dielectric losses in a substance are caused by direct conduction through the substance, by true dielectric absorption in the substance, and in some cases by electrolytic conduction through the substance. For most engineering purposes, however, it is unnecessary to differentiate between these various sources of dielectric loss. The total dielectric loss of a substance is expressed in terms of the power factor of that substance. The power factor of a condenser made up with a good dielectric between its plates will be small, that is, the current and voltage will be almost in quadrature. For this reason this property of a dielectric is often defined by the phase-defect angle or dielectric-loss angle which is the small angle by which the current through and the voltage across the test condenser depart from exact quadrature.

The determination of dielectric constant and power factor requires the measurement of the capacitance and power factor of a test condenser in which the space between the plates is first filled with air and then with the substance under investigation. The dielectric constant will be the ratio of the latter capacitance to the former, and the power factor will be the power factor of the condenser when the dielectric is the substance under investigation. The power factor of a properly constructed air condenser will be zero to a high degree of precision. In the case of solids it is preferable to use a test condenser whose capacitance can be computed. It should be remembered that the computed capacitance will be in electrostatic units and the measured capacitance will be in electromagnetic units. For a parallel-plate condenser the dielectric constant is given by the formula

$$K = \frac{11.3Ct}{S} \tag{42}$$

where K is the dielectric constant, C is the measured capacitance (in micromicrofarads)

of the test condenser made from the substance under test, t is the thickness of the specimen in centimeters, and S is the area of the condenser plates in square centimeters.

MEASUREMENT OF DIELECTRIC CONSTANT AND POWER FACTOR AT RADIO FREQUENCIES. The measurement of dielectric constant and power factor at radio frequencies calls for special technique. In Fig. 51, which shows a circuit for this purpose, L represents a suitable radio-frequency inductor, C_s a standard adjustable condenser of known or negligible losses, C_x a condenser made from the material under test, T and G a shielded thermo-element galvanometer. The galvanometer G should be a sensitive low-resistance instrument whose deflections within reasonable limits are proportional to the square of the current in the heating element. The points 1, 2, 3, 4, 5, 6 are points of a special mercury-cup switch into which are inserted short-circuiting links or the terminals of special non-inductive resistors.

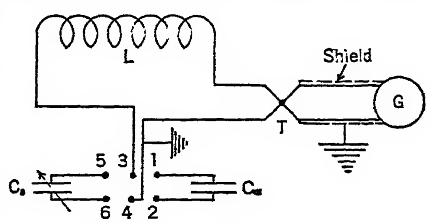

FIG. 51

Short-circuiting links are inserted between the points 1–3 and 2–4, a suitable radio-frequency generator of known frequency is coupled inductively to the coil L, and the circuits are tuned to resonance. The deflection of the galvanometer is then noted when the short-circuiting links are in place and again when a series of suitable non-inductive resistors are inserted between the points 1–3 and 2–4. The equivalent resistance of the circuit is then computed from the equation

$$R = \frac{R_1}{[d_0/d_1 - 1]^{1/2}} \tag{43}$$

where R is the equivalent resistance of the circuit, R_1 is the resistance inserted, d_0 is the galvanometer deflection with the short-circuiting links inserted, and d_1 the galvanometer deflection with R_1 inserted.

Short-circuiting links are now inserted between 3–5 and 4–6 and the circuit tuned to resonance with C_s, the generating circuit being left unchanged. The capacitance of C_s now gives the capacitance of C_x. The equivalent resistance of the circuit containing C_s is now determined as before. The difference between the two equivalent resistances just determined will give the equivalent resistance of the condenser C_x, since C_s is assumed to have negligible resistance.

The power factor in percentage is then computed from the equation

$$\text{Power factor (in percentage)} = 6.283 \times RCf \times 10^{-7} \tag{44}$$

where R is the equivalent resistance of the sample condenser in ohms, C is the capacitance of the sample condenser in micromicrofarads, and f is the test frequency in kilocycles.

The dielectric constant K is computed from the equation

$$K = \frac{11.3Ct}{S} \tag{45}$$

where C is the capacitance of the sample condenser in micromicrofarads, t is the thickness of the specimen in centimeters, and S is the area of the sample condenser (parallel-plate condenser) in square centimeters. For further details of the measurements see the Bibliography.

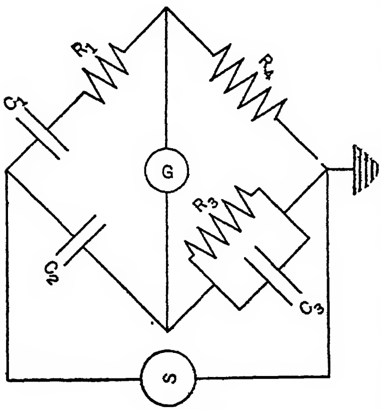

FIG. 52

MEASUREMENT OF DIELECTRIC LOSS AT HIGH VOLTAGES: THE SCHERING BRIDGE. One of the most important measurements in modern high-voltage technology is the determination of the dielectric losses in samples of insulating materials under high dielectric stress. For such measurements the Schering-bridge method has great technical advantages and may now be regarded as the standard method. Referring to Fig. 52, C_1 is the effective capacitance and R_1 the equivalent series resistance of the imperfect condenser to be tested, C_2 is a standard no-loss

condenser which must be capable of withstanding the full test voltage, C_3 is an adjustable condenser, and R_3 and R_4 are non-reactive resistors. When the bridge is balanced so that no current flows through the detector circuit G, it can be shown that

$$R_1 = \frac{C_3}{C_2} R_4 \tag{46}$$

and

$$\tan \theta_1 = \omega R_3 C_3 \tag{47}$$

Here θ_1 is the loss angle of the tested condenser, by which its phase angle differs from 90 deg, and ω is 2π times the frequency. A knowledge of the capacitance of C_2 is not necessary for a determination of the power factor of C_1, but it is essential that the losses of C_2 be negligible or known. In actual practice, C_1 and C_2 are small and consequently these arms are of high impedance in comparison with the two remaining arms. If E is the voltage applied to the bridge, the power loss in the branch containing the unknown condenser (C_1, R_1) is given to a high degree of approximation by the expression

$$\text{Power in watts} = E^2 \omega^2 R_3^2 \frac{C_2 C_3}{R_4} \tag{48}$$

MEASUREMENT OF DIELECTRIC LOSS WITH COMPENSATED ELECTRODYNAMIC WATTMETER. It is sometimes convenient to measure the dielectric loss of a specimen with a compensated electrodynamic wattmeter. The circuit is shown in Fig. 53. The test sample is subjected to a high voltage from a test transformer, and the power absorbed by it is measured by means of a sensitive reflecting wattmeter. The phase angles of the voltage transformer and the wattmeter voltage coil $V.C.$ are compensated by means of a condenser C. The effective capacitance of this condenser may be varied by changing the value of the shunting resistance r. Before making a test a zero-loss air condenser is substituted for the test sample and the resistance r varied until the wattmeter shows zero deflection. The test sample is then substituted for the air condenser and the test repeated, the deflection indicating the power lost in the sample. To measure the current, the voltage coil of the wattmeter is connected across the resistance S, through the variable resistance R_c. This puts the current in the two coils in phase and the instrument will read as an ammeter. The wattmeter is calibrated by direct current, using a potentiometer and standard cell.

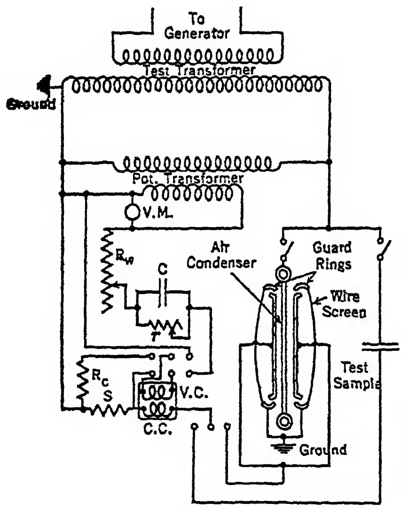

FIG. 53

SHIELDING OF BRIDGE CIRCUITS. In using such a-c bridges as have been described, both at radio frequencies and at power frequencies, the proper shielding of the bridge circuit is of as great importance as the choice of a suitable bridge circuit. See references on Shielding and Guarding Instruments and Circuits in the Bibliography.

USE OF CATHODE-RAY OSCILLOGRAPH IN DIELECTRIC RESEARCH. Although not capable of as great precision as the Schering bridge, the cathode-ray oscillograph is a powerful instrument for the investigation of short-time phenomena in dielectric researches. In using it, a voltage in phase with the voltage across the specimen is applied to one of the pairs of deflection plates, and a voltage in phase with the current through the specimen is applied to the other pair of plates. The electron beam is deflected by the fields resulting from these voltages and, upon striking a fluorescent screen or photographic plate, traces a figure, generally an ellipse, whose shape is determined by the phase relation existing between the deflecting voltages. When a pure sine-wave voltage is applied to an imperfect condenser the beam traces an ellipse from whose area and orientation the power factor can be deduced. See the article on Cathode-Ray Oscillograph.

21. PHOTOMETRY

Considering light as radiant energy evaluated according to its capacity to produce visual sensation, the chief aspects of photometry are the determination of (*a*) luminous intensity (candlepower) of light sources in a single direction, (*b*) candlepower distribution of light sources, usually in the horizontal and vertical planes, (*c*) luminous flux from light sources, (*d*) illumination of surfaces, (*e*) brightness of surfaces, (*f*) reflecting properties of surfaces, and (*g*) transmission properties of substances. Of these (*f*) and (*g*) are determinations of the properties of materials, and together with (*b*) can be made without reference to any standard since they can be expressed as ratios and not in terms of any units. All the other determinations, however, must be made directly or indirectly against primary or fundamental reference standards of light.

PRIMARY STANDARDS OF LIGHT. A primary standard of light is one by which the unit of light is established and from which the values of other standards are derived. A satisfactory primary standard must be reproducible from specifications.

Electric Lamps. Precise photometry dates from the adoption of electric incandescent lamps as standards in 1909. An agreement, entered into in 1909 by the National Bureau of Standards, the National Physical Laboratory, and the Laboratoire Central d'Électricité, brought the photometric units of the United States, England, and France to a single value, within the limits of experimental error. These national standardizing laboratories agreed to maintain the new unit constant and to call it the international candle. This name was formally adopted by the International Commission on Illumination in 1921. It was not specified in the agreement of 1909 how the new unit was to be maintained, but the agreement had been reached by the consideration of results of international comparisons of carbon-filament lamps, and the unit has since been maintained by means of carbon lamps. It is assumed that the average luminous intensity of the lamps maintained by each laboratory has not changed since individual values were assigned to the lamps in 1909. Numerous intercomparisons have shown that this assumption is not ill-founded.

Waidner-Burgess Standard of Light. Electric incandescent lamps maintain their values over long periods of time and are convenient to use, but their use as primary or fundamental standards is not justifiable in theory. The National Bureau of Standards has recently proposed as a suitable primary standard, the Waidner-Burgess standard of light (See *Bur. Standards J. Research*, vol. 6, pp. 1103-1117, June, 1931, reprinted as Bur. Standards Research Paper 325.) It consists of a black-body radiator immersed in platinum heated to a temperature slightly above its melting point and allowed to cool. When the freezing point is reached, the temperature remains constant thereafter until all the platinum is frozen; the temperature of the black body and its brightness also remain constant. The brightness of a black body at the freezing point of platinum (1773.5 deg cent) is reported by the Bureau of Standards to be 58.84 candles per sq cm.

Flame Standards. Standard candles are no longer of practical importance. The name of the unit of luminous intensity was derived from these earliest standards. The only flame standards of practical importance now are the Hefner lamp and the Harcourt 10-cp pentane lamp. These are used, respectively, in Germany and other continental European countries, and in England.

The **Hefner standard lamp** is a wick lamp burning amyl acetate of very high purity. It is equipped with an optical device so that its flame can be adjusted very accurately to the correct height of 40 mm. A variation of 1 mm in the height of the flame causes 2.7 per cent change in candlepower. In its use, allowance must be made for atmospheric pressure and humidity according to the formula

$$I = 1 + 0.0055(8.8 - e) - 0.00011(760 - b) \tag{49}$$

where I is the luminous intensity of the lamp in Hefner Kerze when burning in an atmosphere at a pressure of b millimeters of mercury, with a humidity of e liters of water vapor per cubic meter of air. A correction is also necessary for the amount of CO_2 in the atmosphere, but it is best to obviate the necessity for this correction by arranging efficient ventilation of the room in which the lamp burns.

The **Harcourt 10-cp pentane standard lamp** is essentially an argand burner supplied with pentane-air gas and preheated air. The fuel is formed by passing air over pentane in a saturator box subdivided by baffles. Under standard atmospheric conditions, viz.: a barometric pressure of 760 mm and a humidity of 8 liters of water vapor per cubic meter of air at a temperature of 15 deg cent, the pentane standard lamp is considered to have a luminous intensity of 10 candles. Corrections for differences from the atmospheric conditions specified are made in accordance with the formula

$$I = 10[1 + 0.0052(8 - e) - 0.00085(760 - b) + 0.001(15 - t)] \tag{50}$$

where e and b have the same meaning as above in the case of the Hefner lamp, I is the luminous intensity of the lamp in international candles, and t is the temperature in degrees centigrade.

SECONDARY STANDARDS OF LIGHT. A secondary standard is one calibrated by comparison with a primary standard. For want of a satisfactory reproducible primary standard the unit of light, the international candle, is maintained at the National Bureau of Standards by means of 45 carbon-filament lamps, which are loosely designated as the "primary" standards. Photometric measurements as generally made are all in terms of secondary standards which derive their assigned values from the "primary" lamps whose values were agreed upon in 1909. Certified lamps can be obtained from the National Bureau of Standards and from testing laboratories.

WORKING STANDARDS OF LIGHT. A working standard of light is any standardized luminous source for daily use in photometry. Electric incandescent lamps as working standards are superior to all other types of lamps. After being properly aged, lamps are standardized for candlepower and current at a definite voltage. The standardization can then usually be relied upon as long as the current taken by the lamps has not changed when the lamps are operated at the originally assigned voltages.

VISUAL PHOTOMETRY. In visual photometry, the eye is used to compare the brightnesses of two surfaces. Because of its power of adaptation to different brightnesses, the eye cannot *measure* light with any degree of accuracy. Measurements must therefore depend on a *judgment of equality* of brightness of two surfaces. These surfaces are presented, usually side by side, to the eye for comparison by means of a photometer. Visual photometers now in general use are of three general types, according to the method of comparison employed, viz.: (1) by equality of brightness of two surfaces visible simultaneously, (2) by equality of contrast between two pairs of surfaces visible simultaneously, and (3) by disappearance of flicker when two surfaces are viewed in rapid succession. Besides serving the purpose of presenting two surfaces to the eye for comparison, photometers must supply a means for varying the brightness of one or both of these surfaces according to some known law, so that a photometric balance may be obtained. The most common methods of doing this are: (1) varying the distance of one or both light sources from the surface compared, according to the inverse-square law of illumination; (2) interposing a rotating sector disk or other absorbing media between one of the light sources and the surface it illuminates; and (3) polarizing the light from the two surfaces in planes perpendicular to each other and using a Nicol prism, capable of rotation, to obtain a photometric balance. Combinations of these methods are commonly used.

PHOTOMETER HEADS OR SIGHT BOXES. An optical device, variously called a photometer head, sight box, or simply "the photometer," is used to make a precise judgment of the equality of brightness or contrast of two surfaces illuminated by different sources. It consists of two diffusing surfaces, each illuminated by one of the sources of light, with accessories to facilitate the comparison and to enable the eye to view the two surfaces simultaneously. The surfaces are often called photometer screens. Many photometer heads or sight boxes have been devised.

INVERSE-SQUARE METHOD OF PHOTOMETRY. If a source of candlepower I_1 is at a distance d_1 from a surface S_1, the illumination on S_1 is I_1/d_1^2 (if the light is incident perpendicularly). If the reflection factor of S_1 is ρ_1, the brightness of S_1 is $I_1\rho_1/d_1^2$. Similarly, if a source of candlepower I_2 is at a distance d_2 from a surface S_2 of reflection factor ρ_2, the brightness of S_2 is $I_2\rho_2/d_2^2$. If these two surfaces are of equal brightness,

$$\frac{I_1\rho_1}{d_1^2} = \frac{I_2\rho_2}{d_2^2} \tag{51}$$

Hence, if ρ_1 and ρ_2 are equal

$$\frac{I_1}{I_2} = \frac{d_1^2}{d_2^2} \tag{52}$$

If I_2 is known, and d_1 and d_2 are measured, I_1 can be calculated. This method of comparing directly I_1 against I_2 assumes that the sources are point sources, that the light is incident normally on the surfaces, and that the reflection factors of the surfaces are equal. These assumptions sometimes would lead to appreciable errors. This difficulty may be obviated by the use of the substitution method. In this a third source whose candlepower must be constant, but need not be known, is used as a comparison lamp on one side of the photometer head, while the two sources to be compared are placed in turn on the other side of the photometer. A photometric balance with the comparison lamp is made in each case. If the candlepower of the comparison lamp is assumed to be I_c, then the required ratio

$$I_1/I_2 = (I_1/I_c)/(I_2/I_c). \tag{53}$$

I_c cancels out, and the required ratio is obtained independent of any lack of symmetry

in the photometer. Usually, also, the distance between the photometer head and comparison lamp is fixed, so that the brightness of the comparison surface is constant. If, then, photometric balance be obtained with the photometer head at distances d_1, d_2, and d_3, from sources of candlepower I_1, I_2, and I_3, respectively, $I_1/d_1^2 = I_2/d_2^2 = I_3/d_3^2$. Much calculation is thereby avoided. Such photometric measurements are made on a photometer bench.

ROTATING SECTOR DISK: TALBOT'S LAW. By Talbot's law, if a disk with an angular aperture in it be rotated between a lamp and a photometer head so that the light from the lamp reaches the photometer screen for only a certain fraction of the time, and if the rotation be so fast that the eye perceives no flicker, the effective candlepower of the lamp is reduced in the ratio of the time of exposure to the total time. If the aperture of the disk is a sector of angle θ degrees, the effective candlepower is reduced by the factor $\theta/360$. The sector disk has advantages over other absorbing media in that it is not affected by time and is independent of color.

SQUARED-TANGENT LAW OF POLARIZATION. The use of this law in photometry involves the production of images of the two surfaces to be compared, by means of an optical train which includes a device for plane polarizing the light from the two surfaces in planes perpendicular to each other. If then an analyzing Nicol prism be interposed in the path of these polarized planes the intensity of one image will be reduced by the factor $\cos^2\theta$ and that of the other image by the factor $\sin^2\theta$, where θ is the angle between the optic axis of the Nicol prism and the plane of polarization of the light forming the first image. If, therefore, the analyzing Nicol be rotated until a photometric balance is obtained at the angle θ, it follows that the ratio of the brightnesses of the two images, with no Nicol interposed, would be $\tan^2\theta$.

BUNSEN PHOTOMETER. In the Bunsen photometer the screen is a disk of white diffusing paper, a well-defined region of which is made translucent by impregnation with oil or paraffin. The disk is set transversely in a sight box, as shown on the plan in Fig. 54. The interior of the sight box is blackened. Light from the lamps to be compared enters the apertures A–A, and falls normally on the disk surfaces. Dihedral mirrors M_1 and M_2 enable both sides of the disk to be viewed at the sight tube T. The opaque portion of the disk reflects diffusely, while the translucent region partially reflects and partially transmits the light received. A photometric balance exists when the two sides of the disk appear alike. If both lamps are alike in color and both regions of the disk have the same absorption, the boundary disappears and both sides appear uniformly bright. With unequal absorption, balance exists when equal contrast exists between the opaque and translucent regions on both sides of the disk. The contrast principle is of distinct advantage with slight color differences. The sensitiveness of the screen depends largely on the definition of the boundary of the impregnated portion.

The Bunsen photometer was the first really accurate photometer devised. It is not as sensitive, however, as later types of photometers, chiefly because each of the surfaces receives light from both sources being compared. This difficulty is avoided in the photometers described below. The Leeson disk is a modification of the Bunsen screen.

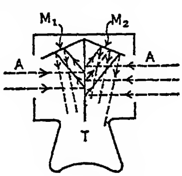

Fig. 54

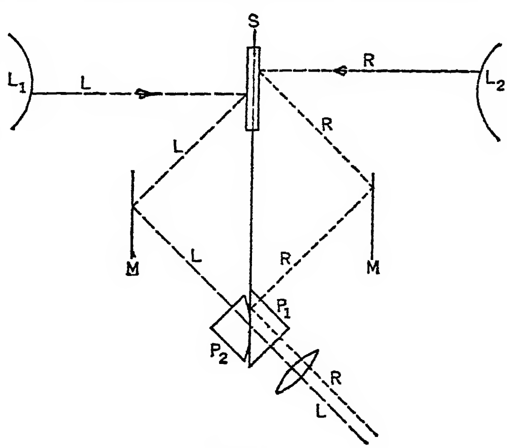

Fig. 55

LUMMER-BRODHUN HEAD OR SIGHT BOX. The plan of this box is shown in Fig. 55. An opaque diffusely reflecting screen S receives light from the sources to be compared and reflects it along the paths indicated by aid of the mirrors M–M and the prisms P_1–P_2, often referred to as a Lummer-Brodhun cube. The prisms present to the eye a

composite field in which the brightnesses of the two sides of S can be conveniently compared. Fig. 55 also shows the arrangement for equality-of-brightness working. The prisms are in optical contact over an elliptical portion of their hypotenusal faces, and the remainder of one is cut away. The central portion of the field is illuminated by direct transmission through the contact area, the outer portion by total reflection from the face of the uncut prism.

For equality-of-contrast working, the arrangement of the prisms is as shown in Fig. 56. The hypotenusal face of P_2 is recessed over an area that provides a pattern as shown in (B). The face of P_1 is plane. Two thin glass absorbing strips C_1 and C_2 are set before the faces of P_1 and P_2 as shown in the plan. The two trapezoids L and R are darkened by the absorption of light in C_1 and C_2. In a state of balance L' and R' appear equally bright and L and R equally dark in contrast. The degree of contrast created by C_1 and C_2 is ordinarily about 8 per cent. Accuracy of adjustment and cleanliness of all parts are essential in photometers of the Lummer-Brodhun type.

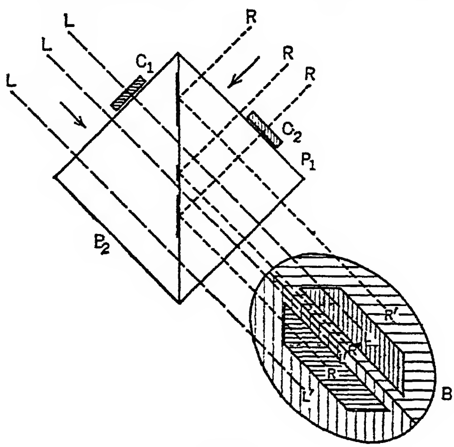

Fig. 56

PHOTOMETER BAR FOR MEASUREMENT OF LUMINOUS INTENSITY (CANDLEPOWER). The devices above described are best suited for use in connection with a fixed photometer bar in a laboratory. Using the substitution method of photometry the most convenient arrangement of the equipment is as shown in Fig. 57. The photometer head P and the comparison lamp C are clamped to a movable carriage so that the distance between them is constant. The carriage can be moved with respect to the lamp socket T which is fixed on the bar. Lamp C is maintained at constant voltage throughout any series of measurements. Working standard lamps and test lamps whose candlepower is to be determined are in turn placed in socket T and maintained at any desired voltage while photometric balance is obtained by setting the movable carriage. In precision photometry, more than one standard is used. A common procedure is to use a set of

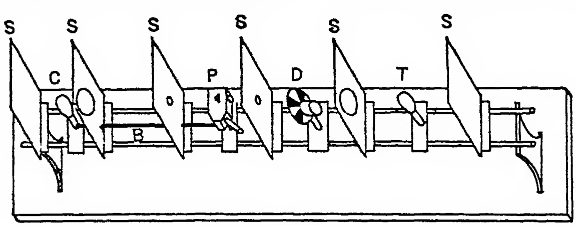

Fig. 57

six working standards, reading three at the start of a run and the other three after the test lamps have been read.

For measurements of candlepower in a fixed direction the lamps must be mounted so that they may be oriented on the bar in that direction. For measurements of mean horizontal candlepower, socket T is rotated at about 120 rpm. The bar should be provided also with a series of screens S of dead black material (preferably velvet) having graded apertures along the photometric axis, and with solid screens at the ends. These screens should completely exclude all extraneous light from the photometer head and should protect the eye of the observer from the direct light of the lamps. If these conditions are met the photometric room need not be blackened, although it is advisable to keep it as dark as is convenient.

PORTABLE PHOTOMETERS. Many forms of portable photometers and illuminometers are available for use both in the laboratory and for measurement of candlepower and illumination in the field. Such instruments are the Sharp-Millar photometer, Macbeth

illuminometer, Holophane light meter, and the foot-candle meter. The Weston illuminometer, a photoelectric-cell device, is the most recent development. The Weber portable photometer, Martens polarization photometer, Bechstein universal photometer, and Bechstein illuminometer are also well-known types

PHOTOMETERS AND ILLUMINOMETERS BASED ON INVERSE-SQUARE LAW. The Sharp-Millar photometer, the Macbeth illuminometer, and the Weber photometer are portable inverse-square-law photometers, consisting essentially of a tube a foot or more in length, a comparison lamp of low voltage, designed to operate on a storage battery or dry cells, a Lummer-Brodhun cube of special design, and a diffusing glass photometer screen. In the Sharp-Millar and Macbeth photometers the comparison lamp is movable; in the Weber photometer the screen is movable. The instruments are provided with scales (graduated according to the inverse-square law) the range of which may be extended by means of neutral filters that can be placed on the test side or comparison side of the cube. An external test plate or standard surface is placed at the point at which illumination is to be measured. The illuminated test plate then serves as the second comparison screen. For details of these photometers see the papers listed in the bibliography.

MARTENS POLARIZATION PHOTOMETER. In this type of photometer, a Fresnel biprism is used to get contiguous images of the surfaces to be compared. In Fig. 58 such a biprism together with a Wollaston prism is shown diagrammatically. Here S_1 and S_2 are the surfaces to be compared. The light from S_1 passes through a plano-convex lens C into a Wollaston prism P. Here it is split up into two beams: one, shown by the full line, is polarized in the plane of the paper; the other, shown by the broken line, is polarized in a plane perpendicular to the paper. The light from S_2 is treated similarly, and the angle of the biprism is designed so that images of S_1 and S_2 oppositely polarized coincide at the eye, while the remaining six images are stopped by a diaphragm. It follows that one-half of the biprism B appears bright because of the light from S_1 which is polarized in the plane of the paper, while the other half appears bright because of light from S_2, which is polarized in a perpendicular plane. A Nicol prism and graduated circle capable of rotation about the axis of the instrument complete the photometer.

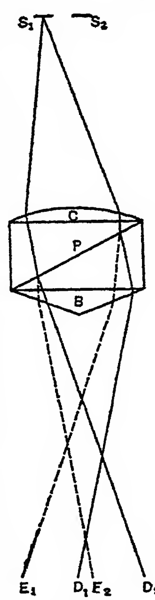

FIG. 58

FOOT-CANDLE METER. A foot-candle meter is a convenient, inexpensive, and self-contained device for making approximate measurements of illumination. It consists of a small metal box, part of whose top consists of a paper screen, opaque except for a row of Bunsen spots on it. The under surface of this screen is illuminated by a small lamp fed by three tubular dry cells. This lamp is at one end of the box, so that the Bunsen spots decrease in brightness from the end where the lamp is placed. Measurement is made by observing which spot disappears when the scale is illuminated from above.

HETEROCHROMATIC PHOTOMETRY. The illuminants in use today, i.e., vacuum and gas-filled tungsten-filament lamps, arc lamps, mantle gas lamps, and gaseous-discharge lamps, give light different in color from that of the fundamental reference-standard lamps. The measurement of the light emitted by modern lamps therefore involves, somewhere in the process, heterochromatic photometry, i.e., photometry with a color difference.

If the eye is required to decide when equality of brightness or equality of contrast exists between the comparison surfaces, with a color difference existing, it encounters a difficulty which increases as the color difference becomes greater.

Cascade Method. One method of bridging the color difference is the cascade method. It involves dividing up the color difference by making the photometric settings in a number of steps. When lamps of efficiencies different from the efficiency of carbon lamps are to be measured against carbon-filament standards it is possible to divide the color difference into a number of steps, by using lamps operating at intermediate efficiencies. Tungsten lamps are blue in color in comparison with the carbon-filament standards, but by reducing the voltage on tungsten lamps a series of color steps can be interposed between the carbon standard and the tungsten test lamp.

Compensation Method. In the compensation or mixture method the color difference is reduced by illuminating one or both of the comparison sources with light from both the sources being compared.

Flicker-Photometer Method. A reliable means of comparing two lights of different colors is the flicker photometer, in which the comparison field is alternately illuminated

by the two sources of light to be compared. This alternate illumination causes a flicker which is due to difference of color and difference in brightness. Above a certain moderate rate of alternation the color sensations blend and the disappearance of flicker is a true indication of equal brightness. The following conditions are required for high precision: (*a*) a field illumination of about 25 meter-candles; (*b*) a photometric field of 2 deg diameter; and (*c*) a background field about 25 deg in diameter surrounding the photometric field and about equal to it in brightness.

The Ives-Kingsbury flicker photometer consists of an ingenious attachment to a Lummer-Brodhun contrast-type photometer, described above, with the contrast glasses removed. It consists essentially of an optical train including (*a*) a lens for magnifying the field, (*b*) a rotating prism, (*c*) a disk with a hole limiting the field to 2 deg, (*d*) an eye lens, and (*e*) a lamp for illuminating the background field. For a complete description of this photometer see *J. Franklin Inst.*, 1915, vol. 180, p. 215.

The Ives-Kingsbury photometer, and most of the other flicker photometers, have so many optical parts that the brightnesses of the comparison surfaces are very materially reduced. Where only low illuminations of these surfaces are available, this is a distinct disadvantage. The Guild flicker photometer obviates this difficulty. It has no optical parts between the eye and the comparison surfaces. These surfaces are (1) a stationary surface of magnesium oxide illuminated by one source and (2) a rotating sector disk of magnesium oxide illuminated by the second source. The stationary surface is viewed through the rotating disk, whose speed of rotation can be adjusted. Thus the eye sees alternately the stationary surface and the sector disk, the two comparison surfaces. The sight tube is arranged so as to supply the background illumination. For a complete description of the Guild flicker photometer, see *J. Sci. Insts.*, 1924, vol. 1, p. 182.

Color-Equalizing Filters. Where a large color difference exists between two sources to be compared directly, flicker photometry gives results which are more consistent and dependable than those obtained by the use of the equality-of-contrast photometers, which are, however, much more convenient and easy to use. If two sources of light to be compared are of different color, the color difference can be removed by placing a suitably colored filter between the photometer and one of the sources and so causing the light from this source to match that from the other source. The problem of heterochromatic photometry is thus reduced to one of homochromatic photometry and can be handled very conveniently with a Lummer-Brodhun photometer. It then becomes necessary to determine the transmission factor of the filter for light of the color given by the source with which it is used. The transmission factor of the filter can be determined by means of a flicker photometer, or by a spectrophotometer.

SPECTROPHOTOMETRY. In ordinary photometry, the light emitted by a source is measured as a whole, regardless of its spectral distribution. In spectrophotometry, the light emitted by the source under examination is compared, wavelength for wavelength, with that given by a standard source. If the spectral distribution of the light given by the standard source is known, the spectral distribution of the light from the test source can be obtained. The acetylene flame has frequently been used as a standard but a tungsten-filament lamp is a more convenient standard of reference. A tungsten lamp is slightly selective as a radiator, and when vacuum lamps are used as reference standards they are operated at a definite "color temperature," as for example at a color temperature of 2360 deg K, and gas-filled lamps at 2680 or 2848 deg K. The "color temperature" of a lamp is the temperature of a black body that gives light of the same color as given by the lamp.

To make a measurement, it is necessary to disperse the light by some device, such as a prism, and then measure the intensity of each wavelength, or in practice, a small group of wavelengths, as compared with the reference standard. A spectrophotometer consists essentially of (1) a device for analyzing the light of each source and making a photometric comparison of the two sources for each small group of wavelengths, and (2) auxiliary equipment for changing the brightness of the components of the field to obtain photometric balance.

Spectrophotometric measurements are particularly applicable to the determination of the spectral transmission of colored filters. From such measurements, the overall transmission of a filter for light of known distribution of energy can be calculated if the spectral characteristics of the average eye are known, for the eye responds very differently for different wavelengths, its limits of sensitivity being about 400 and 750 millimicrons, with the maximum sensitivity at 550 millimicrons. The most generally accepted values of the relativity sensitivity of the "average eye" are those proposed by Gibson and Tyndall, which have been provisionally accepted for international use by the International Commission on Illumination. (See Illuminating Engineering Nomenclature and Photometric Standards, A.S.A., Z7-1932, p. 8, for Table of Values of Relative Visibility (V_λ).

MEASUREMENT OF CANDLEPOWER DISTRIBUTION AND LIGHT FLUX. No actual light source is a point source, so no light source used in practice has the same luminous intensity (candlepower) in all directions. Therefore the measurement of the candlepower of a source of light in any one direction gives no information as to the light output of the source, or the distribution of the light. The determination of the luminous intensity of an incandescent lamp in, say, 18 directions (10-deg intervals) in the horizontal plane and in the vertical plane is sufficient for plotting polar curves of light distribution. To make such determinations, various arrangements of mirrors and means for rotating the lamp and mirrors have been devised. A typical three-mirror device is shown diagrammatically in Fig. 59. The lamp may remain stationary or be rotated about its vertical axis. The mirrors may be turned about the horizontal photometric axis in steps.

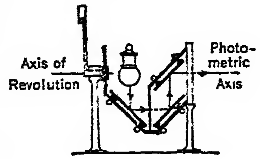

FIG. 59

The mean spherical candlepower or lumen output of an incandescent lamp may be determined: (1) by measuring the candlepower of the lamp in many directions in space and computing the mean; (2) by measurement of mean horizontal candlepower, and computation by using the reduction factor; and (3) by measurement of total flux or mean spherical candlepower in an integrating-sphere photometer.

Total flux of luminaires may be measured with sufficient accuracy for general purposes by making candlepower measurements on a distribution photometer at the middle of each 10-deg zone, from 0 to 180 deg, angles being measured counter-clockwise from the "six o'clock" position. If then the mean candlepower for each 10-deg zone be multiplied by zone factors, which are the zonal areas on the unit sphere, total lumens for any zone or the complete sphere can be computed.

INTEGRATING-SPHERE PHOTOMETER. An integrating-sphere photometer (Ulbricht sphere) provides the means of making measurements of mean spherical candlepower or total flux of light in lumens from a lamp or luminaire by a single observation, if a standard of luminous flux is available for comparison. Sphere photometers range in size from 15 in. diameter to 100 in. or even more. The inside of the sphere is painted with a specially prepared white paint, as non-selective as possible and of highest diffusing power obtainable.

When a lighted lamp is put into the sphere, the illumination on any element of area A of the sphere wall is made up of two parts: (1) the direct light from the lamp E_d; and (2) the light diffusely reflected, E_r, from all parts of the sphere wall. The component E_r of the total illumination on A is proportional to the total flux of the source and independent of the location of the source within the sphere. It is sufficient therefore to measure the component E_r. This is done by inserting a small translucent glass window flush with the inner surface of the sphere wall, and screening the window from the direct light of the source by the smallest screen that will completely cut off all direct light from the window. The sphere window then serves as a transmitting test plate, and its brightness may be measured by a suitable arrangement of a bar photometer, with Lummer-Brodhun cube, or by means of a portable photometer.

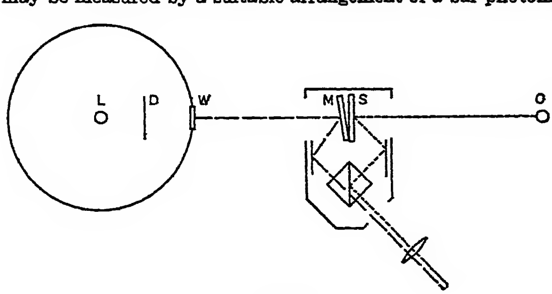

FIG. 60

Fig. 60 is a diagrammatic sketch showing a commonly used method for visual readings. The mirror M in the Lummer-Brodhun sight box makes the external sphere-window surface W one of the comparison-screen surfaces. The photometric balance is obtained by moving the comparison lamp, C keeping the photometer head fixed. Other arrangements are also used.

The substitution method is used in making measurements, standards of luminous flux and the test lamps or luminaires to be measured being placed in the sphere in turn, and photometer settings made, either visually or by physical photometry (photoelectric-cell methods). Auxiliaries such as sector disks and colored glass filters are easily applied.

Attention to details is essential. The sphere window should be non-selective in transmission, have good diffusing qualities, and be no larger than about one-tenth the

sphere diameter and preferably smaller. The shield in the sphere between the source and window must be so located and of such size as to reduce to a minimum the area of the sphere wall from which first reflections cannot reach the area, but fully screen all direct light of the source. If the source is at the center of the sphere, the best position of the screen is at a point 0.387 times the radius of the sphere from the window. All objects in the sphere introduce errors, including the lamps to be measured, particularly if such lamps are blackened from use, or if the test lamps differ much in size from the standards. The paint should be non-selective and renewed periodically.

Sphere-photometry errors are discussed at length by Weigel and Knoll in a paper in *Licht und Lampe*, 1928, vol. 17, p. 753.

MEASUREMENT OF BRIGHTNESS, REFLECTION FACTOR AND TRANSMISSION FACTOR. Measurement of Brightness. Brightness is defined as the quotient of the luminous intensity of a surface, measured in a given direction, by the area of this surface projected on the plane perpendicular to the direction considered. The brightness of an illuminated surface or transmitting medium may therefore be obtained by measuring the candlepower of the surface in a given direction and dividing this value by the projected area. However, this direct method is applicable practically only to very bright sources. For illuminating engineering purposes the brightness of surfaces may be measured satisfactorily with a Macbeth or Sharp-Millar portable photometer. The scale of the photometer is ordinarily calibrated in foot-candles to read illumination on a test plate. If the reflection factor of the test plate is known the photometer may be calibrated to read brightness directly, if scale readings are multiplied by the quantity ρ/π, where ρ is the reflection factor of the test plate. Test plates of magnesium oxide or magnesium carbonate (reflection factor 98 per cent), freshly prepared, are useful in such calibrations.

Measurement of Reflection Factor. The measurement of reflection factors is most readily made by means of a Taylor reflectometer. This instrument consists of a small integrating sphere from which a segment has been cut away, and a lighting tube, containing a lamp and lens in a movable mounting so fixed into the sphere that the spot of light produced by the lamp and lens in the tube may be projected either on the wall of the sphere, or on the test surface to be measured, the test surface forming that part of the wall of the sphere that has been cut away. Into a third opening in the sphere the sight tube of a Macbeth illuminometer is inserted. A small screen prevents light from the directly illuminated surface from falling on the observed point on the sphere wall. Readings are taken when the beam illuminates the test surface and when it illuminates the sphere wall directly. The ratio of the readings is the reflection factor.

The Taylor reflectometer may be used for measuring reflection factors of polished surfaces (regular reflection) and reflection factors of matt, diffusing surfaces. The reflection factor of a material depends upon the color and the direction of the incident light.

Measurement of Transmission Factor. The measurement of transmission of transparent media has been discussed under spectrophotometry. For illuminating engineering purposes, the transmission factor of enclosing diffusing globes and other types of glassware is of importance. It is commonly spoken of as the "efficiency" of the glassware. Measurements are most conveniently made in a large integrating sphere, by measuring, first, the lumen output of the bare lamp, and then the lumen output of the lamp in its inclosing equipment. The inverse ratio of the measured values is the percent transmission, or "efficiency." In making such measurement, the inclosing unit should be placed somewhere in the sphere while the working standard lamps and the test lamp to be used in the inclosing globe are measured.

PHOTOMETRY OF PROJECTION APPARATUS. The photometric measurement of light projectors, such as automobile headlamps, airway beacons, airport and hangar floodlights, locomotive headlamps, searchlights, and general floodlighting equipment, constitutes a special problem. The approval by state authorities of automobile headlamp devices has brought about the development by testing laboratories of special equipment for the measurement of candlepower distribution in headlamp beams. A photometric range of 100 ft is desirable. The Sharp-Millar, Macbeth, or Bechstein portable photometers with accessory equipment are suitable for making candlepower-distribution measurements to determine compliance of types of headlamps with special state requirements or with the standard specification of the American Standards Association covering the laboratory testing of automobile headlamp devices. (See Specifications of Laboratory Tests for Approval of Electric Headlighting Devices for Motor Vehicles. Illum. Engng. Soc., New York, A.S.A. Tentative Standard D2-1922. See also Joint IES-SAE Standard, *Trans. Illum. Engng. Soc.*, 1930, vol. 25, p. 835).

In making candlepower measurements on projectors, it is usually the case that the whole aperture of the projection device is filled with light and appears equally bright

all over. The area of the projector opening is therefore the source, and the values determined are in terms of apparent candlepower, measured at a specified distance. The apparent candlepower of an extended source of light, measured at a specified distance, is the candlepower of a point source of light which would produce the same illumination at that distance.

For floodlighting equipment and airway beacons, maximum beam candlepower, lumen output in the beam, and horizontal and vertical angular beam spread are required. Reference may be made to the General Procedure for Photometry of Incandescent Floodlights, *Railway Electrical Engineer*, 1927, vol. 18, p. 315, where full and detailed description of methods of measurement and computation tables will be found.

For locomotive headlighting see the Report of the Committee on Locomotive Electric Lighting, *Railway Electrical Engineer*, 1924, vol. 15, p. 335.

PHOTOELECTRIC-CELL PHOTOMETRY. The very rapid development of photoelectric cells within recent years has made photoelectric-cell photometry practicable for use in testing laboratories and in incandescent lamp factories, and, by the application of certain types of cells to portable instruments (illuminometers), for use in making illumination measurements in the field.

A photoelectric-cell photometer, in its simplest form, consists of a light-sensitive cell, one or more electric batteries, a suitable protective resistor (10 to 100 megohms), and a galvanometer. Both gas-filled and vacuum photoelectric cells are used in photometry. The electric current produced is very small, and for photometers for routine use amplification is desirable. An ideal photoelectric cell for photometric use should have, among others, the following characteristics: (*a*) The electric current produced by the cell when illuminated should be directly proportional to the illumination of the cell. This property is commonly called "linearity of response." (*b*) The response of the cell from day to day should be constant. (*c*) The color sensitivity should be the same as the color sensitivity of the average eye. By careful selection of cells and by the use of filters all these conditions can be met satisfactorily for practical use. Manufacturers of photometric apparatus now supply photometers equipped with photoelectric cells and auxiliary devices complete for laboratory installation as well as several types of portable photometers.

Reproducibility of results by photoelectric-cell photometers is much better than by visual photometers. Great care is necessary, however, for the elimination of disturbing influences. The cell and electron tubes must be carefully and completely shielded, and leakage caused by moisture must be guarded against. Dark rooms are not necessary for photoelectric-cell photometry. Candlepower distribution, transmission, and color temperature methods are being developed.

22. ELECTRICAL RECORDING INSTRUMENTS

A recording instrument is defined as an instrument which makes a graphic record of the value of an electrical quantity as a function of time. The term "recording instrument" may be replaced by the shorter term "recorder." For other definitions, and some of the more general requirements to be met, see A.I.E.E. Report on Standards for Electrical Recording Instruments, No. 40, June, 1933.

An electrical recording instrument produces and controls the motion of a marking device which leaves a record on a chart advanced at a controlled speed by clockwork, a synchronous motor, or equivalent. The operating forces set up by nearly all indicating-instrument mechanisms are so small that the attempt to make them move a pen over a chart, without serious errors from pen friction, is beset with difficulties. The design must be modified to secure a relatively high operating torque (or force), even at the cost of increased power required for operation. This difficulty is obviated, though at the expense of complication and increased cost, in relay-type recording instruments, in which the marking device is moved by a secondary driving force controlled by the moving element. By this means it is possible to measure small electrical quantities which would not be able to operate a direct-acting recording instrument, as in relay-type recording potentiometers.

Recording instruments are made in many forms and for an ever-increasing list of applications in industrial processes for which accurate control of conditions is essential to the maintenance of quality, minimum cost of production, or both. For detailed descriptions and operating instructions the makers' publications should be consulted. Detailed treatments of the construction of the various types of recording instruments are given in the books and articles listed in the Bibliography.

23. TELEMETERING

The A.I.E.E. Committee on Instruments and Measurements defines "telemeter" as "Measuring, transmitting and receiving apparatus for indicating, recording or integrating at a distance by electrical means the value of a quantity." The art of telemetering ("remote metering" or, in British usage, "distant indication") came into existence as a matter of necessity as the interconnection of systems became more widespread and the control of scattered power plants became more centralized. In 1926 the importance of the subject prompted the setting up by the A.I.E.E. Committee on Instruments and Measurements of a subcommittee to survey the field and collect information. The reports of this subcommittee should be consulted (see Bibliography) for recommended definitions of terms and the classification of remote-metering systems. A subcommittee of the A.I.E.E. Automatic Stations Committee cooperated with the subcommittee on telemetering in the preparation of a report on telemetering and supervisory control systems and related communication systems. At this writing (1936) this report has been published only in mimeographed form.

24. MEASUREMENT OF NON-ELECTRICAL QUANTITIES BY ELECTRICAL AND MAGNETIC MEANS

Electrical and magnetic means and measuring instruments have been applied for a vast number of kinds of measurement of non-electrical quantities. These have been classified by Borden (see Bibliography), as follows:

1. Measurement of temperature.
2. Measurement of stress, strain, or small changes in physical dimensions.
3. Measurement of flow of liquids and gases.
4. Measurement of angular and of linear velocity.
5. Measurement of work.
6. Measurement of radiant energy.
7. Determination of chemical and molecular condition.
8. Navigational measurement, and detection of hidden conditions.
9. Physiological and allied measurements.

The number of measuring devices coming under these nine headings is so great that reference must be made to the paper by Borden, which contains a valuable bibliography of 330 entries. A paper by H. L. Curtis, immediately following Borden's paper, gives a detailed account of the manner in which moving-coil oscillographs were used to measure the important quantities relating to the firing of heavy guns on shipboard, for example, the velocity of the projectile and the time-displacement curve of the gun during recoil.

At the Winter Convention of the A.I.E.E. in January-February, 1929, a session was devoted to electrical measurement of non-electrical quantities, with papers by Sanford, Pratt, Miner and Batten, Spooner and Folta, and Marriott (see Bibliography). For subsequent A.I.E.E. papers on the measurement of noise of machinery, see Bibliography.

25. MEASUREMENT OF TEMPERATURE

THE PRIMARY STANDARD SCALE OF TEMPERATURE. The International Temperature Scale, adopted by 31 nations in 1927, is based upon a number of fixed and reproducible equilibrium temperatures to which numerical values are assigned, and upon the indications of specified interpolation instruments calibrated according to a specified procedure at the fixed temperatures. This scale conforms, as closely as is possible with present knowledge, with the Thermodynamic Centigrade Scale, on which the temperature of melting ice, and the temperature of condensing water vapor, both under a pressure of 1 atmosphere, are numbered 0 and 100 deg, respectively. Temperatures on the international scale are ordinarily designated by the abbreviations deg cent, °C, or C. By a recently approved American Tentative Standard (ASA Z10i-1932) the abbreviation C denotes a temperature scale or points thereon, but numbers expressing *intervals* on this scale are followed by the abbreviation °C.

THE FAHRENHEIT SCALE. This scale is now derived from the international scale by means of the relations

$$t_f = \frac{9}{5} t_c + 32 \tag{54}$$

$$t_c = \frac{5}{9} (t_f - 32) \tag{55}$$

where t_f = temperature in degrees fahrenheit.
t_c = temperature in degrees centigrade.

A degree fahrenheit is abbreviated deg fahr, °F, or F.

OTHER TEMPERATURE SCALES. A number of other temperature scales have been used or proposed, of which only the Réaumur survives to any extent in the United States. In this scale, the interval between the ice and steam points is taken as 80 deg, the ice point being 0 deg R.

ABSOLUTE TEMPERATURE SCALES. Thermodynamic reasoning introduces the concept of absolute temperature, on which basis a temperature of − 273.1 deg on the International Temperature Scale would be called zero temperature absolute. The two absolute temperature scales are: the centigrade absolute or Kelvin scale, abbreviated °K or K, and the fahrenheit absolute or Rankine scale, abbreviated °R′. A temperature in degrees centigrade absolute is numerically equal to the same temperature in degrees centigrade plus 273.1, and a temperature in degrees fahrenheit absolute is numerically equal to the same temperature in degrees fahrenheit plus 459.6.

Thermometers

CHOICE OF THERMOMETERS. The selection of a thermometer for a particular purpose is governed by the temperature range to be covered, the precision required, the nature of the substance whose temperature is to be measured, the space available, and the type of reading (indication or record) desired.

LIQUID-IN-GLASS THERMOMETERS. For the measurement of temperatures below about 500 deg cent, in applications not requiring the high accuracy obtainable with precision thermocouples and resistance thermometers, liquid-in-glass thermometers are extensively used. The fluids generally used are alcohol, pentane, toluene, and mercury, the first three being used for temperatures below the freezing point of mercury. For all temperatures above its freezing point, mercury is much superior to the other liquids.

Mercury-in-glass thermometers are made in various ranges, and are of all grades as to quality of the glass and of workmanship. For engineering and laboratory measurements, thermometers of the laboratory type (sometimes called chemical thermometers), having the scale marked directly on the tube, are preferable to those in which the scale is not integral with the tube. The latter type, if of good workmanship, is suitable for industrial use where only moderate accuracy is required.

Mercury-in-glass thermometers are made to cover the range − 35 to 550 deg cent. By using fused silica instead of hard glass, the upper limit is extended to 800 deg cent, but such thermometers are very little used. They are fragile and expensive, their emergent-stem correction is large and uncertain, and some other form of pyrometer is much to be preferred.

When using thermometers calibrated for total immersion (i.e., calibrated with the entire liquid column of the thermometer at one temperature) a correction must be applied to the reading if part of the column is in the stem of the thermometer at a temperature materially different from that of the bulb. For mercury-in-glass centigrade thermometers the approximate "emergent-stem correction" is given by the formula

$$\text{Correction} = +0.00016n(t_b - t_s) \tag{56}$$

where the temperatures are in degrees centigrade and n = number of degrees of the column of mercury exposed to the emergent-stem temperature, t_s, and t_b = temperature of the bulb. For more precise corrections see Smithsonian Physical Tables.

RESISTANCE THERMOMETERS. In its usual laboratory form the resistance thermometer consists of a coil of platinum wire wound on a mica frame and enclosed in a protecting tube through which leads are brought out for connection to a bridge for measuring the resistance of the wire. Such thermometers are particularly useful in calorimetry and other laboratory work where high accuracy is required. For technical purposes some form of thermocouple is usually preferable. In the form of embedded temperature detectors resistance thermometers are built into the slots of generators to measure the temperature of the windings during operation.

PRESSURE-GAGE THERMOMETERS. Two types of thermometers are similar in that each has a metal bulb coupled to a pressure gage by a capillary tube. In the vapor-pressure type the bulb contains a liquid which has a measurable vapor pressure in the temperature range for which the thermometer is designed. In the liquid-expansion type the bulb, tube, and gage are completely filled with a liquid. In each case the gage is graduated to read the temperature of the bulb. The vapor-pressure thermometer has the advantage of indicating the temperature of the bulb regardless of the relative volume of the capillary tube and its temperature. It is theorectically unaffected by

leakage of the liquid, so long as some liquid remains in the bulb, but its readings will be affected by leakage of air or other fluid into the bulb. The reading of the liquid-expansion thermometer is dependent on the relative volume and temperature of the emergent stem, and is affected by leakage outward. The liquid-expansion type has the advantage of uniform length of scale divisions.

BIMETALLIC THERMOMETERS. The bimetallic thermometer contains a strip of so-called "thermostatic metal." One end of the strip is fixed, and the motion of the free end with change of temperature actuates the pointer through a magnifying mechanism.

The pressure-gage and the bimetallic thermometers, though especially suitable for recording, are neither as accurate nor as reliable as mercury-in-glass thermometers.

CHECKING THERMOMETERS. The graduation errors of a thermometer can best be determined by comparing it with a secondary standard mercury-in-glass thermometer which has been tested and certified by a competent laboratory, such as that of the National Bureau of Standards in Washington. Only the zero point need be checked subsequently on mercury-in-glass thermometers. This can be done by noting the reading of the thermometer after total immersion for several minutes in a mixture of crushed ice and distilled water. Pressure-gage thermometers, however, may need to be recalibrated frequently over the working range.

PRECISION AND RANGE OF MEASUREMENT OF TYPES OF THERMOMETERS. Typical figures, intended merely to guide in the selection of suitable types, are given in Table IX.

Table IX. Precision and Range of Measurement of Types of Thermometers

Type of Thermometer	Range °C	Precision	
		Best Grade °C	Average Grade °C
Mercury—ordinary	−35 to 300	0.01	0.5
hard glass	0 to 550	0.1	1
Alcohol	−100 to 40	..	1
Electrical resistance	0 to 100	0.002	..
	−200 to 500	0.01	..
	500 to 1200	..	1 to 5
Thermoelectric	−200 to 1000	0.05 to 0.1	1 to 10
Bimetallic	0 to 500	..	1 to 20
Pressure-gage	0 to 750	..	1 to 10

LOCATION OF THERMOMETERS. In locating a thermometer, it must be realized that it indicates its own temperature, which may or may not be that of its surroundings. To indicate the temperature of its surroundings, a thermometer must be in good thermal contact with them; it must not be exposed to radiation from hotter bodies, nor able to radiate to cooler ones; in short, it must not "see" anything which is at a different temperature. Equal precaution should be taken to prevent loss of heat by conduction or convection.

Pyrometers

GENERAL. A pyrometer is a device intended primarily for measuring temperatures beyond the range of a mercury-in-glass thermometer, say above 500 deg cent. Certain types of pyrometers are frequently found useful in measuring lower temperatures also.

Numerous types of pyrometers, now of historical interest only, are treated in detail in Burgess and Le Chatelier's High Temperature Measurements (see Bibliography). This section is restricted to current pyrometric data and devices.

THERMOELECTRIC PYROMETERS. The most widely used pyrometric device consists of a thermocouple and an instrument capable of indicating or recording electromotive force. Although the standard thermocouple, one wire platinum and the other wire an alloy consisting of 10 per cent rhodium and 90 per cent platinum, is used in defining the temperature scale, the majority of couples in actual use are of less expensive materials ("base metals"). The commonly used thermocouples and their ranges of usefulness are given in Table X. Constantan is also sold under a number of trade names, namely, Ia Ia, Ideal, Advance, Copel, Eureka, etc.

TEMPERATURE-EMF RELATIONS FOR VARIOUS THERMOCOUPLES. In Table XI are given representative calibration data for couples of the six types commonly used. These data may be used to obtain approximate temperatures, good to the equivalent of about 0.5 per cent in emf, except for couples having constantan as one element. For more accurate work each individual couple must be calibrated. Values of thermal

Table X. Range of Usefulness of Thermocouples

Type of Thermocouple	Useful Range	
	For Long-time Service	* For Short-time Service
Platinum vs. 90% platinum—10% rhodium...	0 to 1450° C	1700° C
" " 87% " —13% " ...	0 to 1450° C	1700° C
Chromel vs. Alumel..........................	0 to 1100° C	1350° C
Iron vs. constantan..........................	0 to 800° C	1000° C
Chromel vs. constantan.....................	0 to 800° C	1000° C
Copper vs. constantan......................	− 190 to 350° C	600° C

* Thermocouples which have been subjected to these temperatures cannot be depended upon to retain their calibrations and should not be used for accurate work subsequently without being recalibrated.

emf for couples having constantan as one element may differ by as much as 2 per cent from those in the table. However, most thermocouple manufacturers take pains to supply a uniform quality of constantan, and the calibrations of individual couples by a reputable maker can be depended to agree with the curve which he issues within about 0.5 per cent in emf.

COLD-JUNCTION CORRECTIONS. The data in Table XI give the relation between the emf of the couple and the temperature of the measuring junction, when the

17	1628	1477	336				
18	1714	1550	353				

reference junction is at 0 deg cent. In many measurements the reference junction is not at 0 deg cent; for example, when the thermocouple wires are connected directly to the measuring instrument, the temperature of the reference junction is that of the instrument. Since the table shows the change in emf of the couple as the temperature of either junction is changed, it may be used to correct an observed emf to that which would have been observed if the reference junction had been at 0 deg cent. For example, if the observed emf of a copper-constantan couple is 10 mv with the reference junction at 25 deg cent, the table shows that the emf would have been 1 mv greater, that is, 11 mv, if the reference junction had been at 0 deg cent. The temperature of the measuring junction was accordingly that corresponding to 11 mv in the table, that is, 232 deg cent. It can be seen that the correct value is not obtained when one adds the cold-junction temperature, 25 deg cent, to the value in the table, 213 deg cent, corresponding to the measured emf, 10 mv. If the indicator is graduated in temperature, so that the emf is not observed, correction for the cold-junction temperature t'_0 may be made by adding to the observed temperature the quantity $(t'_0 - t_0)K$, where t_0 is the cold-junction temperature for which the thermocouple was calibrated. Values of K for typical couples are as follows:

Table XII. Values of Cold-junction Correction Factor K*

Platinum to Platinum—10% rhodium		Platinum to Platinum—13% rhodium		Copper to Constantan		Chromel to Constantan	
Deg C	K	Deg C	K	Deg C	K	Deg C	K
250–400	0.65	250–400	0.60	0–50	1.00	0–50	1.00
400–650	0.60	400–600	0.55	50–80	0.95	50–100	0.95

1000–1100	1.05	650–750	0.85
1100–1250	1.10	750–900	0.80

* Values of K in this table are based on calibrations with a cold-junction temperature of 0 deg cent.

COLD-JUNCTION COMPENSATORS. Various devices are used to avoid the necessity for making the calculations described in the preceding paragraphs. Simple indicators may be set, on open circuit, to read the emf corresponding to the cold-junction temperature, or the cold-junction temperature itself, depending upon the way the scale is graduated. In many deflection-type instruments this setting is done automatically by means of a bimetallic spiral which moves the outer end of one of the control springs of the moving coil as the temperature of the instrument changes. Potentiometric instruments may be equipped with either manually or automatically operated cold-junction compensators. Evidently, the automatic compensators are effective only if the temperature of the cold junction is the same as that of the instrument. The cold junction may be brought to the instrument by the use of extension leads, which for base-metal couples are of the same materials as the couple. For rare-metal couples the extension leads consist of one wire of copper and one of a suitable alloy of copper and nickel. The extension leads may be carried directly to the indicator, or they may be brought to some point at constant temperature, for example, the bottom of a pipe driven about 10 ft into the ground. When the cold junction is not at the instrument, the compensator setting must correspond to the temperature of the cold junction.

MEASUREMENT OF EMF. The instruments used to indicate or record the emf of thermocouples may be classed as potentiometers (null instruments) and millivoltmeters (galvanometers). Instruments using a combination of the galvanometric and potentiometric principles have been devised but are seldom used.

Galvanometers. Since the emf's are small, the galvanometers must be very sensitive to voltage. This could be accomplished by making the galvanometer coil of low resistance, but on account of the variable line resistance of a thermoelectric circuit it is necessary to make the resistance of the galvanometer as high as possible, consistent with substantial construction. A large part of the resistance should be that of a manganin series resistor in order that the indicated emf may be nearly independent of the temperature of the instrument. If the indicator is graduated to read emf at its terminals the relation between scale reading e_0 and true emf of the couple e becomes

$$e_0 = R_g e/(R_g + R_c + R_l), \tag{57}$$

where R_g, R_c, and R_l denote the resistances of the galvanometer, couple, and lead wires, respectively. If R_g is large compared with $R_c + R_l$ the above equation reduces to $e_0 = e$ approximately and the indicator reads correctly. When R_g is low it is possible to graduate the scale to read true emf for a definite line resistance, but if this changes on account of deterioration of the couple, etc., serious error may result. Thus a 300-ohm indicator designed for use with a 2-ohm line resistance will be in error by only 7 deg at 1000 deg cent if the line resistance changes to 4 ohms, while a 10-ohm indicator under similar conditions would read 140 deg cent too low. This emphasizes the importance of using galvanometers of high resistance. Most pyrometer manufacturers can supply galvanometers (millivoltmeters) with a resistance of several hundred ohms.

The advantages of the galvanometer method are quick reading, simplicity, and moderate initial cost. The disadvantages lie largely in the effects due to thermocouple and lead resistance mentioned above.

Potentiometers. The most accurate instrument for measuring thermoelectric emf's is the potentiometer. Portable potentiometers are available for either rare-metal or base-metal couples, or for both with a double scale. There are several important advan-

tages in the potentiometer method. The emf or temperature scale is easily made very open, thus permitting accurate readings. The calibration of the scale is in no way dependent upon the constancy of magnets, springs, or jewel bearings, nor upon the level of the instrument. From the pyrometric standpoint, however, the greatest advantage is the complete elimination of any error due to ordinary changes in the resistance of the couple or of the lead wires. Thus if a potentiometer is correctly balanced and the resistance of the thermocouple is then greatly increased, the balance is unchanged. However, excessive resistance in the couple circuit reduces the sensitivity of a setting. The objections to the potentiometer are the greater initial cost and the fact that usually a manual adjustment must be made to obtain a setting.

At least four manufacturers are now making recording potentiometers designed for use with thermocouples. In these recorders the balancing is done automatically.

THERMOCOUPLES FOR SPECIAL USES. Many special types of thermocouple adapted for special uses are available. One of these is the pipe-type couple in which one element is a pipe or tube of some metal such as iron or chromel, and the other element is a wire passing through the pipe and insulated from it, except at the closed end where it is welded to the pipe to form the hot junction. There are a number of special types of couple designed for measuring the temperature of molten metals and alloys.

PYROMETER PROTECTION TUBES. In the measurement of high temperatures the choice of a protection tube is nearly as important as the selection of the thermocouple. All thermocouples should be protected from reducing gases, sulfur, and metallic vapors. Only porcelain, quartz, and Pyrex-glass protection tubes should be used for platinum-rhodium thermocouples. Pyrex glass is usable up to 600 deg cent, quartz (fused silica) up to 1000 deg cent, and American-made porcelain (mullite) up to 1550 deg cent. In many cases it is advisable to protect these tubes by an outside or secondary protection tube made of materials such as chromel, nichrome, carborundum, graphite, alundum, nickel, iron, calorized iron, etc. All these tubes have their special uses. Base-metal thermocouples are ordinarily protected by metal protection tubes, but under severe conditions porcelain tubes are used alone or in combination with a metal tube. The thermocouple wires are usually insulated by two-hole porcelain insulating tubes.

AUTOMATIC RECORDERS. The types of pyrometers ordinarily used in the automatic recording of temperatures are (1) resistance thermometers, (2) radiation pyrometers, and (3) thermoelectric pyrometers. Of these the last has the greatest applicability. The type of curve ordinarily required is temperature versus time, in which case the instrument is equipped with a mechanism for periodically recording its indications upon a chart which moves with a uniform speed. Single- or multiple-point recorders operating on either the galvanometric or potentiometric principle are available. Multiple-point recorders are equipped with a commutator switch which automatically connects various thermocouples into the circuit successively.

STANDARD SAMPLES FOR CHECKING THERMOCOUPLE PYROMETERS. In order to enable the user of thermocouple pyrometers to check their indications, the National Bureau of Standards supplies standard samples of metals of certified melting points. Information concerning the samples which could be purchased from the Bureau in March, 1936, is given in Table XIII.

Table XIII. Standard Samples of Metals for Checking Thermocouple Pyrometers

Sample No.	Metal	Melting Point		Weight of Sample in Grams	Price per Sample
		Deg Cent	Deg Fahr		
42b	Tin	231.9	449.4	350	$2.00
43c	Zinc	419.5	787.1	350	2.00
44c	Aluminum	660.2	1220.4	200	2.00
45a	Copper	1083	1981.4	450	2.00
49a	Lead	327.35	621.2	1650	2.00

RADIATION PYROMETRY AND OPTICAL PYROMETRY. Radiation pyrometry and optical pyrometry are based respectively on the intensity of total radiation and of visible radiation from a hot body. Since different substances at the same temperature do not necessarily emit radiation of the same intensity or spectral distribution, this fact must be taken into account in the use of either radiation pyrometers or optical pyrometers. There is one form of radiator, the so-called black body, the radiation from which depends only on its temperature. A uniformly heated enclosure with a small opening, or even a furnace with not too large an opening, constitutes a good approximation to a black body. If the object, the temperature of which is to be measured, is inside

such a black body, or if the radiation comes from a deep cavity in the object, the radiation will depend only on the temperature.

FÉRY MIRROR TELESCOPE PYROMETER. In this instrument radiation of all wavelengths is brought to a focus, by means of a concave gold mirror, upon the hot junction of a minute thermocouple. The cold junctions of the couple are suitably screened from the direct radiation of the hot body. The concentration of heat at the hot junction develops an emf which may be measured by a potentiometer or galvanometer. In practice the galvanometer is usually calibrated to read temperature directly. Foster has transformed the Féry telescope into a fixed-focus pyrometer by placing the thermocouple and a small front diaphragm at the conjugate foci of the gold mirror.

THWING PYROMETER. In the Thwing pyrometer the reflecting mirror is replaced by an aluminum cone which by multiple reflections concentrates the radiation at its apex on one or more small thermocouples in series with a portable galvanometer. The instrument requires no focusing, the front diaphragm acting as a source. The object sighted upon must be large enough to cover the projection of the cone through this diaphragm.

PYRO RADIATION PYROMETER. In the Pyro radiation pyrometer, the radiation is focused by means of a quartz objective lens upon a thermocouple mounted in an evacuated bulb. A "receiving disc" fixed over the thermojunction can be seen in the field of view and must be fully covered by the image of the radiating source. The instrument is very compact and direct reading, the millivoltmeter being mounted in the telescope itself and graduated in temperature directly.

Precautions in the Use of Radiation Pyrometers. The mirrors or other reflecting devices must be kept bright and free from dust. With the Féry pyrometer, errors amounting to 100 deg cent have been observed, on account of ordinary accumulation of dirt upon the large gold mirror. Many radiation instruments require several minutes of exposure to the radiating source to indicate a maximum reading on account of the slow heating of the hot junction; others require less than 20 sec. The maximum indication should be accepted. Care must be taken that the source is large enough to "fill" the aperture of the pyrometer completely and that the pyrometer is focused. It is usually impossible to focus upon the back of a furnace through a very small peephole and obtain reliable results; the hole must be enlarged so that it does not cut into the cone of rays entering the instrument, or the pyrometer may be focused upon the hole itself. In the latter case the hole must be large enough to "cover" the thermocouple in the Féry pyrometer or the front diaphragms of the Thwing and Foster pyrometers. Variations in room temperature in general affect the hot and cold junctions nearly alike, so that very little error is introduced in the reading of a radiation instrument from this cause. It is desirable to employ the same ratio of diameter of source sighted on to sighting distance both in calibration and use of all radiation pyrometers.

Because of the uncertainty of the large correction required when sighting upon non-black bodies, radiation pyrometers are not suitable for measuring temperatures of materials in the open.

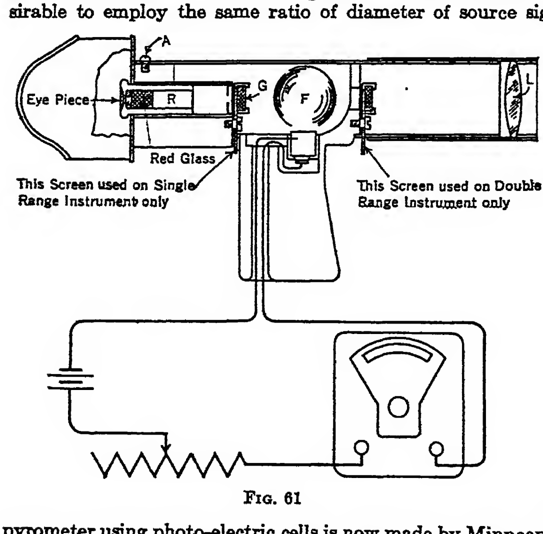

Fig. 61

OPTICAL PYROMETRY. An optical pyrometer is essentially a photometer for comparing the brightness of the red light (λ = approximately 0.65 μ) radiated by a body with that radiated by a comparison source such as an electric lamp. Temperatures on the international scale above 1063 deg cent are defined in terms of such measurements. An automatically recording optical pyrometer using photo-electric cells is now made by Minneapolis-Honeywell Regulator Co.

LEEDS & NORTHRUP OPTICAL PYROMETER. The filament F of a small electric lamp, Fig. 61, is placed at the focus of the objective lens L which superimposes

upon the lamp filament an image of the source to be measured. This image and filament are viewed through the eyepiece *R* which is equipped with a red glass screen. In making a setting the current through the lamp is adjusted until the filament and source appear equal in brightness.

The calibration of the lamp will remain remarkably constant if it is not operated above 1500 deg cent. For higher temperatures an absorption screen is provided between the lamp and objective, which may be thrown in or out of the field of view by a lever. This screen reduces the brightness of the source so that any temperature up to 1800 deg cent. can be matched by the lamp at 1400 deg cent or less. For higher temperatures a second absorption screen is used in combination with the first. Without the absorption screen the calibration gives a relation between lamp current and temperature. With the absorption screen, calibration gives a second relation between lamp current and temperature.

The F & F pyrometer is similar to the Leeds & Northrup instrument except that the current is kept constant at the "normal" value and an absorption wedge between source and lamp is adjusted until sufficient thickness of the wedge has been introduced to reduce the brightness of the source to that of the lamp at normal current. The wedge carries a pointer moving over a scale graduated directly in temperature. This instrument is made with two ranges, the same wedge being used alone or in combination with a fixed absorption glass.

EMISSIVITY CORRECTIONS FOR OPTICAL PYROMETERS. Optical pyrometers indicate the true temperature of black bodies only. A peephole in a furnace or a porcelain tube with the closed end immersed in molten metal or otherwise surrounded by the temperature to be measured may be considered as a black body. When an optical pyrometer is sighted upon objects in the open, corrections must be made in accordance with the following table:

Table XIV. Correction to Observed Temperature Using Red Light

Emissivity	Add Corrections below for the Following Observed Temperatures, deg cent						
	800	1000	1200	1400	1600	1800	2000
0.30	67	95	129	168	213	264	322
0.40	50	71	96	125	158	195	237
0.50	37	53	71	93	117	144	175
0.60	27	39	52	67	85	104	126
0.70	19	27	36	47	59	72	87
0.80	12	17	22	29	36	44	54
0.90	6	8	10	14	17	21	25
1.00	0	0	0	0	0	0	0

Values of the emissivity of a few of the more common materials are given in Table XV.

Table XV. Monochromatic Emissivity, E_λ, for Red Light

($\lambda = 0.65\mu$)

Material	Monochromatic Emissivity E_λ	Material	Monochromatic Emissivity E_λ
Silver	0.07	Nichrome, 900° C	0.90

Keinath, G., New guiding lines for the construction of electrical measuring apparatus. *Zeitschr. Ver. deut. Ingen.*, 1928, Vol. 72, p. 1784. Progress of the technique of measurements in 1917. *Elektrot. Zeitschr.*, 1928, Vol. 49, p. 1.
Drysdale, C. V., Electrical measuring instruments other than integrating meters. *J. Inst. Elec. Engrs.*, 1928, Vol. 66, p. 596; 1931, Vol. 69, p. 170. Indicating electrical instruments. *J. Sci. Instruments* (London), 1932, Vol. 9, p. 209.
Lenehan, B. E., and MacGahan, Paul, Indicating instrument quality. *Elec. J.*, 1929, Vol. 26, p. 520.

Specifications for Electrical Measuring Apparatus

A.I.E.E. Standards No. 14, Instrument Transformers, 1925; No. 33, Electrical Measuring (Indicating) Instruments, 1927; No. 40, Report on Standards for Electrical Recording Instruments, 1933. At this writing (March, 1936) revisions of Standards No. 14 and No. 33 have been prepared but not published. They are being used, with other material, by two sectional committees of the American Standards Association in the preparation of American standards for instrument transformers and for indicating electrical measuring instruments respectively.

Specification 17–I–12 for Instruments, Electrical Measuring, Indicating, for Shipboard Use, Including External Resistors and Instrument Transformers. Issued by the U. S. Navy Dept., Dec. 2, 1929. This is the only American specification containing the numerical values of error limits, influences, etc., necessary in a purchase specification. Copies of this and other Navy Department specifications may be had without charge upon application to the Bureau of Supplies and Accounts, Navy Dept., Washington, D.C. When requesting, reference should be made to the specification by both title and number. A printed list of Navy specifications may be had upon application.

Measurement of Large Direct Currents

Besag, Long-distance measurement of large direct currents. *Elektrot. Zeitschr.*, 1919, Vol. 40, p. 436.
Field, M. B., Multiple-unit shunts for the measurement of very heavy currents. *J. Inst. Elec. Engrs.*, 1920, Vol. 58, p. 661.
Melsom, S. W., and Booth, H. C., Efficiency of end connections, and short-period ratings of large-current shunts. *J. Inst. Elec. Engrs.*, 1925, Vol. 63, p. 299.
Dahlgren, F. A., Meter shunts for heavy direct currents. *Electrician* (London), 1926, Vol. 97, p. 499.
Gonnard, P., Measurement of large direct currents. *Rev. Gén. de l'Élec.*, 1930, Vo.. 27, p. 95.

Rectifier Instruments

Grondahl, L. O., and Geiger, P. H., A new electronic rectifier. *Trans. A.I.E.E.*, 1927, Vol. 46, p. 357.
Goodwin, W. N., Jr., Rectifier-type instruments. *Instruments* (Pittsburgh), 1930, Vol. 3, p. 706.
Hartshorn, L., The frequency errors of rectifier instruments of the copper-oxide type for a-c measurements. *Proc. Phys. Soc. London*, 1930, Vol. 42, p. 521.

Oatley, C. W., Copper-oxide rectifiers ("Some notes on their use in the construction of a-c instruments"). *Elec. Rev.* (London), 1930, Vol. 107, p. 90.
Sahagen, Joseph, Use of the copper-oxide rectifier for instrument purposes. *Proc. Inst. Radio Engrs.*, 1931, Vol. 19, p. 233.
Singh, Kartar, Copper-oxide rectifiers. *Elec. Rev.* (London), 1931, Vol. 109, p. 247.

Grondahl, L. O. The copper-cuprous-oxide rectifier and photoelectric cell. *Rev. Modern Phys.*, 1933, Vol. 5, p. 141.

Electronic (Thermionic) Instruments

Moullin, E. B., A direct-reading thermionic voltmeter and its applications. *J. Inst. Elec. Engrs.* (London), 1923, Vol. 61, p. 295.
Hoare, S. C., A new thermionic instrument. *Trans. A.I.E.E.*, 1927, Vol. 46, p. 541.
Moullin, E. B., Some developments of the thermionic voltmeter. *J. Inst. Elec. Engrs.*, 1930, Vol. 68, p. 1039. Includes bibliography of 16 entries.

Wattmeters

Ellis, A. L., Compensating wattmeters. *Trans. A.I.E.E.*, 1912, Vol. 31, p. 1579.
Lee, E. S., Wattmeter connections. *Gen. Elec. Rev.*, 1916, Vol. 19, p. 212.
Doyle, E. S., Correcting wattmeter readings for phase-angle errors. *Elec. World*, 1921, Vol. 77, p. 314.
Edgerly, H. S., Connections for a three-current-coil wattmeter. *Elec. World*, 1927, Vol. 90, p. 70.
Geyger, W., New ironless electrodynamic precision wattmeter. *Archiv für Elektrot.*, 1927–28, Vol. 19, p. 132.
Auchincloss, John, Various methods of connecting indicating wattmeters. *Gen. Elec. Rev.*, 1928, Vol. 31, pp. 257, 376.
Werres, C. O., A simplified method of applying instrument transformer correction factors to wattmeter readings. *Gen. Elec. Rev.*, 1933, Vol. 36, p. 462.
H & B Promille (0.1 per cent) wattmeter. *Archiv für technisches Messen*, 1933, No. 29, Sheet F29.

Frequency Meters

Pratt, W. H., and Price, D. R., Resonant-circuit frequency meters. *Trans. A.I.E.E.*, 1912, Vol. 31, p. 1595.
St. Clair, B. W., Frequency meters. *Instruments* (Pittsburgh), 1930, Vol. 2, p. 374.
MacGahan, Paul, A new indicating frequency meter. *Instruments* (Pittsburgh), 1930, Vol. 3, p. 197.

Power-factor Meters

Rowell, R. M., Commercial power-factor measurements. *Gen. Elec. Rev.*, 1933, Vol. 36, p. 493.
Edgcumbe and Ockenden, Industrial Electrical Measuring Instruments. 3d ed. Pitman, 1933. Chapter entitled Power-factor or phase meters.

Synchroscopes

Haraden, J. A., The operation and installation of switchboard synchronism indicators. *Gen. Elec. Rev.*, 1913, Vol. 16, p. 262.
Anderson, C., and Lunas, L. J., A low-energy synchroscope. *Elec. J.*, 1933, Vol. 30, p. 167.
Edgcumbe and Ockenden, Industrial Electrical Measuring Instruments. Pitman, 1933. Chapter entitled Paralleling and synchronizing apparatus.

Measurement of Rectified Currents

Todd, Victor H., Selecting ammeters for various current measurements. *Elec. Rev.* (Chicago), 1920, Vol. 77, p. 683.
Geyger, Wilhelm, Measurement of the a-c component of rectified currents by the potentiometer method. *Archiv für Elektrot.*, 1927, Vol. 18, p. 629.
Goodwin, W. N., Jr., Measurement of pulsating currents. *Trans. Soc. Motion Picture Operators*, 1928, Vol. 12, p. 364, reprinted in *Instruments* (Pittsburgh), 1929, Vol. 2, p. 115.
MacGahan, Paul, Measurement of pulsating currents. *Elec. J.*, 1930, Vol. 27, p. 596.

Ohmmeters

Brooks, H. B., Accuracy tests for Meggers. *Elec. World*, 1925, Vol. 85, p. 973.
Geyger, W., Moving-iron quotient meters with circular moving iron. *Archiv für technisches Messen*, 1931, No. 5, Sheet T74. See same journal, 1932, No. 8, Sheet F7, for additional details.

Microfaradmeters

Bercovitz, D., The Weston microfaradmeter. *Elektrot. Zeitschr.*, 1925, Vol. 46, p. 312. See also *Archiv für technisches Messen*, Sheet F2, July, 1931. In this latter article Figs. 1a, 1b, 2a, 2b should be corrected to agree with Figs. 9 and 11 of the article in *Elektrot. Zeitschr.*
Blamberg, E., New iron-cored a-c electrodynamometer without mechanical control and its various possible applications. Part 3, Direct-reading capacitance meter independent of voltage and frequency. *Archiv für Elektrot.*, 1926–27, Vol. 17, p. 308. Same author, New H & B capacitance meter. *Helios*, 1930, Vol. 36, pp. 241, 249. This instrument is further described in *Archiv für technisches Messen*, Sheet F5, Feb. 1932.

Miscellaneous Measuring Instruments

Doyle, E. D., A differential electrodynamometer. *J. Optical Soc. Am.*, 1922, Vol. 6, p. 281.
Camilli, G., A flux voltmeter for magnetic tests (giving indications directly proportional to the maximum flux density, regardless of the wave form of the voltage). *Trans. A.I.E.E.*, 1926, Vol. 45, p. 721.
Camilli, G., Reduction of transformer exciting current to sine-wave basis. *Trans. A.I.E.E.*, 1927, Vol. 46, p. 692. Describes a "crest ammeter" for indicating the instantaneous maximum value of current.
Doggett, L. A., Heim, J. W., and White, M. W., A new wave-shape factor and meter. *Trans. A.I.E.E.*, 1926, Vol. 45, p. 435.

PRINCIPLES OF ELECTROCHEMISTRY

Revised by Martin Kilpatrick and Mary L. Kilpatrick

Electrochemistry is the science which deals with the phenomena resulting from the direct transformation of electrical into chemical energy or the converse transformation of chemical into electrical energy. By general usage the term, especially as applied to industrial processes has come to include also those thermochemical phenomena which occur at temperatures produced in electric furnaces, although in such processes electrical energy frequently plays no other rôle than that of generating heat.

1. DEFINITIONS

The following terms are commonly used:

Element. An element is a substance which cannot be decomposed by the ordinary process of chemical analysis. (See Table of Electrochemical Equivalents, p. 6–06, and International Atomic Weights, Sect. 2.) At present 90 elements are known. In connection with the definition given, it should be added that the radioactive elements undergo spontaneous decomposition into other elements, and that recently certain of the elements have been decomposed by bombardment with alpha-rays, hydrogen nuclei, and neutrons.

Atoms and Atomic Weights. An atom is the smallest mass of an element that can enter into chemical combination with another element or with itself. As a standard, the atomic weight of oxygen has been arbitrarily chosen as 16. The combining or equivalent weight of an element is the weight which combines with 8 parts by weight of oxygen. The atomic weight is identical with, or a simple multiple of, the combining weight, depending on the number of atoms of the element which combine with one atom of oxygen. The number of equivalent weights of an element which constitute its atomic weight is determined from a study of the composition of the gaseous compounds of the element, or from a study of its specific heat. On the atomic theory the atomic weight is proportional to the mass of the atom.

Molecules and Molecular Weight. A molecule is the smallest mass of a substance which can exist and preserve its chemical properties. The molecular weight of an element or of a chemical compound is equal to the sum of the atomic weights of the atoms contained in the molecule, and may readily be calculated from the atomic weights when the molecular symbol of the compound is known. Thus the molecular weight of oxygen, O_2, is $2 \times 16.00 = 32.00$ as there are two atoms in the molecule. The molecular weight of silver nitrate, $AgNO_3$ is $107.88 + 14.01 + 3 \times 16.00 = 169.89$.

Radical. A radical is a combination of two or more elements which persists as a group in chemical reactions, e.g., the SO_4 in H_2SO_4 is a radical, as exemplified by the reaction $H_2SO_4 + Zn = ZnSO_4 + H_2$.

Formula Weight. The formula weight of an atom, radical, or molecule is the sum of the atomic weights of the elements of which it is formed. For example, the formula weight of an oxygen atom, O, is 16; the formula weight of an oxygen molecule, O_2, is 32; the formula weight of the radical NO_3 is $14.01 + 3 \times 16.00 = 62.01$.

Valence. An adequate consideration of valence would involve a discussion beyond the limits of this article. As a simple definition, the valence of an element may be taken as the number of hydrogen atoms, or atoms of an element such as chlorine which combines with hydrogen atom for atom, combining with an atom of the element in question. Thus from the formulas H_2O, HCl, KCl, $BaCl_2$ the valences of oxygen, chlorine, potassium, and barium are seen to be 2, 1, 1, and 2, respectively. The valence of a radical is similarly defined; for example, the formulas KNO_3 and H_2SO_4 show that the nitrate radical has a valence of 1, the sulfate radical, a valence of 2. Acids are classified as mono-, di-, or tribasic according to the number of replaceable hydrogen atoms which they contain (cp. HCl, H_2SO_4, H_3PO_4). Bases are classified as mono-, di-, or triacidic (KOH, $Ba(OH)_2$, $La(OH)_3$). Salts are classified as uni-univalent (KCl), bi-univalent ($BaCl_2$), uni-bivalent (K_2SO_4), bi-bivalent ($BaSO_4$), etc.

The valence of an element may vary, cp. the cupric compounds (CuO, $CuCl_2$, etc.)

in which the valence of copper is 2, and the cuprous compounds (Cu_2O, $CuCl$, etc.) in which the valence of copper is 1.

Equivalent Weight—Chemical Equivalent. The equivalent weight of an atom, ion, or radical is defined as its formula weight divided by its valence. The equivalent weight of an element or compound is also referred to as its "chemical equivalent." The equivalent weight of an acid, base, or salt is its molecular formula weight divided by the valence of the ion of higher valence. As hydrogen exhibits no other valence than unity its equivalent weight and atomic weight are identical. Similarly, the equivalent weight and molecular weight of hydrochloric acid, HCl, are each 36.47. Copper in copper sulfate, $Cu(SO_4)$, and in cupric chloride, $CuCl_2$, has a valence of 2; hence equivalent weights of these salts are one-half their molecular weights respectively.

In computations of electrochemical reactions it is frequently convenient to take as the unit of mass (or weight) of a substance, a mass in grams equal to the number expressing the atomic weight, ionic weight, molecular weight, or equivalent weight of the substance. The following names have been given these units.

Gram-atom or Gram-atomic Weight. The number of grams of an element equal to its atomic weight, e.g., one gram-atom of oxygen is 16 grams.

Gram-molecule or Mol. The number of grams of a substance equal to its molecular weight, e.g., one mol of silver nitrate, $AgNO_3$, is 169.89 grams.

Gram-equivalent. The number of grams of an atom, radical, or molecule equal to its equivalent weight. For example, a gram-equivalent of sulfuric acid is $\frac{1}{2}\,H_2SO_4 = \frac{1}{2}\,98.09 = 49.04$ grams.

Electrolyte, Electrolysis. When an electric current is passed through certain substances known as electrolytic conductors a chemical reaction occurs at the places where the current enters and leaves, and there is a transfer of matter through the substance. Fused salts, and aqueous solutions (or solutions in other ionizing solvents) of acids, bases, and salts, belong in the class of electrolytic conductors. The acid, base, or salt in question is called an electrolyte, and the process of the passage of a current through an electrolytic conductor is known as electrolysis. It is important to note that an electrolyte is ionized before the current is passed.

Electrodes. Electrodes are the conductors by which the current enters and leaves the electrolyte or its solution. The electrode at which the current enters is called the "anode," and that by which the current leaves is called the "cathode."

Ions. Anions and Cations. The constituents of an electrolytic conductor which conduct the current through the solution or the fused salt are called ions. They exist in the conductor before the passage of the current, and during the passage of the current the positively charged ions or cations travel toward the cathode, and the negatively charged ions or anions travel toward the anode.

The charge of an ion is proportional to its valence. Each individual univalent anion bears a charge of one electron; each bivalent anion, a charge of two electrons, etc. Each univalent cation has a deficit of one electron or a positive charge of magnitude equal to that of an electron; each bivalent cation has a deficit of two electrons, etc. The value of the electron, as determined by Millikan, is 4.774 ± 0.005 electrostatic units. See Handbook of Engineering Fundamentals, Eshbach, John Wiley & Sons, Inc., "Electron Theory."

To distinguish ions from neutral particles, small plus or minus signs are written after the symbol, the number of such signs being equal to the valence of the ion. Thus Cl^- represents a gram-atom of chlorine bearing a charge of an equivalent of negative electricity or N electrons, N being Avogadro's number. An equivalent of negative electricity is designated as $(-)$. Ca^{++} represents a gram-atom of calcium having a deficit of $2N$ electrons or $2(-)$.

Ionic Weight. The formula weight of an ion is called its ionic weight.

Gram-ion. The number of grams of an ion equal to its ionic weight, e.g., one gram-ion of hydrogen is 1.008 grams, and one gram-ion of SO_4 is 96.07 grams.

Electrochemical Equivalent. The electrochemical equivalent of an ion is the mass in grams of the ion liberated or deposited by one coulomb of electricity.

Electrochemical Constant or "Faraday." The electrochemical constant, denoted by F, and called the "faraday," is the number of coulombs required to produce one equivalent of chemical change. It is a constant for all ions. Its value is $96{,}500 \pm 10$ coulombs (International Critical Tables, vol. 1, p. 17).

Solvent, Solute, and Solution. A solution is formed if upon mixing substance A with substance B a homogeneous or one-phase system results. For dilute solutions, it is customary to refer to the substance present in great excess as the solvent, and to the other as the solute.

Osmotic Pressure. The osmotic pressure of a solution is the pressure which must

be exerted upon it in order that the vapor pressure of the solvent from the solution be the same as the vapor pressure of the pure solvent at the temperature in question. See section below on Theory of Solutions.

Specific Conductance (κ). The specific conductance of a solution is the reciprocal of its specific resistance, i.e., it is the conductance of a column of liquid 1 cm long and 1 sq cm cross-section. It is expressed in reciprocal ohms, or mhos, and is denoted by κ.

Concentration. The composition of a solution may be expressed in a number of ways, of which the more common are listed below.

(*a*) For a solution composed of n_1 gram-molecules of X_1, n_2 of X_2, . . . n_r of X_r, the mol fraction of the *i*th component is given as $N_i = \dfrac{n_i}{\sum_{j=1}^{r} n_j}$.

(*b*) The number of gram-molecules of X per liter of solution is called the molarity of X.

(*c*) The number of gram-molecules of X dissolved in 1000 grams of solvent is called the molality of X.

(*d*) The concentration of X may be expressed as the number of grams of X contained in unit volume of the solution.

(*e*) The number of gram-equivalents of X in unit volume of solution is called the equivalent concentration. The symbol η is used here to represent the number of equivalents per cubic centimeter of solution.

Dilution (ϕ). The dilution of a solution is the number of cubic centimeters of solution in which one gram-equivalent of solute is dissolved. It is denoted by ϕ. Hence $\phi = 1/\eta$ and $\eta = 1/\phi$.

Normal Solution. A normal solution is a solution containing one gram-equivalent of solute per liter. For such a solution $\eta = 10^{-3}$ or $\phi = 1000$.

Equivalent Conductance (Λ). The equivalent conductance of a solution at the dilution ϕ is the conductance which a volume (in cubic centimeters) of the solution containing one gram-equivalent of the solute would have, if placed between parallel plate electrodes 1 cm apart. It is denoted by Λ_ϕ or Λ_η, according as the dilution or concentration of the solution is given. Hence $\Lambda_\phi = \phi\kappa$, or $\Lambda_\eta = \kappa/\eta$.

The dilution or concentration of a solution should always be stated in connection with its equivalent conductance, otherwise the expression is indefinite.

Heat of Reaction. The heat of reaction is the heat energy given out or absorbed in a chemical reaction. It is usually expressed in calories. Ostwald recommends the use of a calorie equal to 100 times the mean gram-calorie for expressing thermochemical data, and this will be adopted in the present discussion. It will be denoted in this article by "cal."

Exothermic Reactions. Reactions in which heat is given out to the surrounding bodies.

Endothermic Reactions. Reactions in which heat is absorbed from the surrounding bodies.

2. NOTATION

For convenience of reference the symbols most frequently used are tabulated below.

κ = specific conductance in reciprocal ohms.
η = concentration, expressed as gram-equivalents of solute per cubic centimeter solution.
ϕ = dilution, expressed as cubic centimeters of solution per gram-equivalent solute.
Λ = equivalent conductance.
Λ_0 = equivalent conductance at infinite dilution.
α = degree of ionization.
E = electrical potential difference.
I = current strength.
r = resistance.
e = single potential difference, taken positive in direction of rise of potential.*
e_h = potential difference measured against a normal hydrogen electrode.
e_c = potential difference measured against a normal calomel electrode.
R = gas constant per mol.
F = the Faraday = 96,500 coulombs per gram-equivalent.
T = absolute temperature in degrees centigrade.
t = centigrade temperature.

* This convention is in agreement with that used elsewhere in this book, and with that employed in The International Critical Tables, see vol. 6, p. 332.

3. CHEMICAL EQUATIONS

A chemical equation, such, for example, as that representing the solution of zinc in a dilute hydrochloric acid solution (Aq = water),

$$Zn + 2\,HClAq = ZnCl_2Aq + H_2,$$

is to be interpreted as follows: one gram-atom (65.37 grams) of zinc reacting with 2 mols ($2 \times 36.47 = 72.94$ grams) of hydrochloric acid in aqueous solution forms one mol ($65.37 + 2 \times 35.46 = 136.3$ grams) of zinc chloride in solution and one mol ($2 \times 1.008 = 2.016$ grams) of hydrogen gas. Since atomic weights are relative numbers, any unit of weight, as the pound or kilogram, may be substituted for gram in this statement.

If the reaction is intended to express not only the chemical change which takes place, but also the energy change involved, the " heat of the reaction " must be included, thus:

$$Zn + 2\,HClAq = ZnCl_2Aq + H_2 + 342 \text{ cal.}$$

This thermochemical equation signifies that the intrinsic energy represented by the initial system, consisting of 65.37 grams of zinc and 72.94 grams of hydrochloric acid dissolved in enough water to form a dilute solution, is 342 calories (1 gram of water from 0 to 100 deg cent) greater than that represented by the final system, consisting of 136.3 grams of zinc chloride dissolved in water and 2.016 grams of hydrogen gas; in other words, when the substances in the initial system react and form the substances in the final system, an amount of heat energy is evolved equal to 342 cal. When energy is given up by a system to the surroundings (exothermic reactions), as in the above illustration, it is regarded as positive. If a reaction is accompanied by an absorption of heat energy (endothermic reactions), i.e., if the system takes up heat and thereby tends to cool the surroundings, the sign of the heat of the reaction is taken as negative.

4. FARADAY'S LAWS

The quantitative relations between the magnitude of an electric current and its chemical effect were discovered by Faraday in 1834 and are known as Faraday's laws. They may be stated as follows:

FIRST LAW. The amount of chemical change produced by an electric current is directly proportional to the total quantity of electricity which passes through the electrolytic cell. The amount of chemical change is independent of the voltage and intensity of the current, size of electrodes, and concentration of electrolyte, so long as the total *quantity* of electricity flowing through the circuit remains constant. (These factors, however, do affect the *ultimate products* of an electrolysis.)

SECOND LAW. A given quantity of electricity always decomposes *equivalent* weights of different electrolytes irrespective of their nature.

Faraday's laws are the expression of the results of direct experiment and have been tested to the limit of precision with which physical and chemical measurements are capable of being carried out at the present time. All evidence indicates that they hold rigidly, i.e., that they are exact laws of nature. In cases where exceptions have seemed to exist these have been shown to arise from secondary causes. See Kraus, *Trans. Am. Elec. Chem. Soc.*, 21, 119 (1912) for special cases of electronic and ionic conduction.

VALUE OF THE ELECTROCHEMICAL CONSTANT OR FARADAY. The determination of the number of coulombs required to deposit one gram-equivalent of an ion, i.e., the constant connecting the quantity of electricity and the mass of a substance liberated, involves two distinct investigations: first, the measurement of the number of coulombs which pass through a given electrolytic cell; and second, the determination of the amount of the chemical decomposition. For a résumé of work on this subject, see *Bull. Bur. Standards*, 13, 497 (1916). The Bureau of Standards gives 96,503 coulombs as the most probable value of the faraday, and recommends 96,500 as the best round value. The International Critical Tables, vol. 1, p. 17, gives $96{,}500 \pm 10$ coulombs.

5. ELECTROCHEMICAL EQUIVALENTS OF THE ELEMENTS

From the definitions of the electrochemical equivalent and the faraday, it follows that the electrochemical equivalent of any ion, expressed in grams per coulomb (one ampere per second), is equal to

$$\frac{\text{gram-equivalent of the ion}}{96{,}500}$$

Table 1 contains the values of the electrochemical equivalents of the more common elements which may be found useful in certain calculations. The electrochemical equivalent of any radical may be readily calculated from its formula; for example, the electrochemical equivalent of SO_4 is

$$(32.06 + 4 \times 16.00)/2 \times 96{,}500 = 0.0004978 \text{ gram or } 0.4978 \text{ milligram.}$$

Table 1. Electrochemical Equivalents of the More Important Elements

Based on the atomic weights of 1935 (*J. Am. Chem. Soc.*, 57, 787, 1935) and on $F = 96{,}500$ coulombs.

Element	Symbol	Atomic Weight	Valence	Milligrams Deposited by One Ampere in One Second	Grams Deposited by One Ampere in One Hour

6. CONDUCTIVITY OF ELECTROLYTES

SOLUTIONS. (See also article on Resistance and Conductance.) The specific conductance of an electrolytic solution varies between wide limits. It depends upon the nature of the solute and of the solvent, on the temperature, and on the concentration of the solution. The effect of these factors is discussed below. For numerical values see Kohlrausch and Holborn, Leitvermögen der Elektrolyte; Landolt-Börnstein, Tabellen; Tables Annuelles Internationales de Constantes; and the International Critical Tables.

FUSED ELECTROLYTES. Most inorganic salts conduct electrolytically when heated to a sufficiently high temperature to cause them to pass into the liquid state. For such electrolytes Faraday's, Ohm's, and Joule's laws hold as they do in the case of solutions. The conductance increases in general from 1 to 1 1/2 per cent per degree centigrade. An exhaustive résumé of all matters relating to fused electrolytes may be found in Lorenz's Elektrolyse der Geschmolzene Salze. On account of their enormous concentration (100 per cent) the specific conductance of fused salts is generally very high. This, together with the difficulty of obtaining a non-conducting chemically inert vessel of suitable shape to contain the salt and the difficulty of regulating high temperatures to a fraction of a degree, makes the measurement of the conductivity of fused electrolytes far more difficult than in the case of solution. Fused silica and natural quartz crystals have been successfully used for conductivity cells. See Jaeger and Kapma, *Z. anorg. Chem.*, 113, 27 (1920); Arndt and Ploetz, *Z. physik. Chem.*, 110, 237 (1924); Biltz and Klemm, *ibid.*, 110, 318 (1924); Lorenz, *Z. Elektrochem.*, 30, 371 (1924); and for further references, Taylor, Treatise on Physical Chemistry, vol. 1, pp. 624–628.

7. VOLTAIC AND ELECTROLYTIC CELLS

When a cell formed by two electrodes and one or more electrolytes gives out electric energy the cell is called a " voltaic " cell. All ordinary chemical batteries are voltaic cells. If across the terminals of a cell an external electromotive force, greater than the electromotive force developed within the cell, is impressed, then a current will flow through the cell in the opposite direction, and the cell will absorb electric energy. A cell which absorbs electric energy is usually referred to as an " electrolytic cell." The cells used in electrolytic refining and similar processes are electrolytic cells. An electrolytic cell may or may not have an electromotive force on open circuit, but may develop an electromotive force by virtue of the chemical changes or changes in concentration which take place due to the current forced through it from some external source. A voltaic cell becomes an electrolytic cell when the electromotive force impressed across its terminals exceeds (and opposes) its own electromotive force.

8. POLARIZATION

When an electric current passes through either a voltaic or an electrolytic cell, in general, there is developed at the electrodes of the cell, as a result of the chemical actions and changes in concentration which take place, a *back* or *counter electromotive* force, in addition to its open-circuit electromotive force (if any), and an *increase in the resistance* of the cell, in addition to the change in resistance due to the heating effect of the current. Both of these effects cause a decrease in the strength of the current through the cell. These two phenomena are said to be due to " polarization " and " transition resistance " respectively.

Even in the case where the electrolyte, as a whole, suffers no change in concentration, as in the electrolysis of copper sulfate between copper electrodes, a counter emf of polarization is produced in consequence of the difference in concentration of the copper ions in the neighborhood of the anode and cathode. Vigorous stirring of the electrolyte tends to reduce this concentration difference and the resulting polarization, but except for very low current densities, it cannot be completely eliminated. It is for this reason, in refining processes, that energy is required to transfer the metal from anode to cathode in addition to that necessary to overcome the internal resistance of the cell.

A transition resistance results from the formation of a film of poorly conducting material over the electrode and may or may not be present according to the character of the electrolysis.

MEASUREMENT OF EMF OF POLARIZATION AND TRANSITION RESISTANCE. As both transition resistance and polarization tend to cut down the current flowing through the cell, they cannot be distinguished by this effect alone. The transition resistance may be determined by measuring the ohmic resistance of the cell before and after the passage of the current by the usual alternating-current method. The existence of an emf of polarization in a cell which normally has no open-circuit emf may be qualitatively demonstrated by short-circuiting the cell through a galvanometer immediately after breaking the primary circuit; if the cell be polarized, a current which diminishes to zero will flow through it in the reverse direction. A voltmeter, or, better, an electrometer connected across the electrolytic cell, will indicate the polarization voltage the instant after the current is broken. This voltage will diminish as the polarization disappears, the rate depending upon the current through the voltmeter and the rate of diffusion of

the electrolytic products causing the polarization. Owing to the rapidity with which the emf of polarization falls off after the exciting cause is removed, special precautions must be observed in its measurement. One of the best methods is to connect the circuit containing the applied emf and electrolytic cell with a tuning-fork interrupter and electrometer so that at the instant the battery current is broken at each vibration of the fork, the circuit containing the cell and electrometer or voltmeter is closed, and vice versa. By this arrangement, the emf of polarization is measured during the fraction of a second that the battery circuit is open, and before it has had time to diminish sensibly. The polarizing current may also be regarded as practically constant.

It is frequently of importance to know, not the polarization of the cell as a whole, but the polarization at each electrode. This is obtained by measuring the drop in potential at each electrode against a normal hydrogen or calomel electrode while the impressed emf is acting on the electrolytic cell, or immediately after the current through the cell is interrupted.

9. REVERSIBLE ELECTRODES—DEPOLARIZERS

If the chemical and thermal actions which take place at a given electrode when a given quantity of electricity passes in one direction through a cell are exactly the reverse of the actions which take place when the same quantity of electricity passes through it in the opposite direction, the electrode and the solution with which it is in contact are said to form a "reversible electrode." Such an electrode does not polarize provided the concentration of the solution is kept constant.

There are two types of reversible metal-liquid electrodes, namely:

Electrodes of the First Type, consisting of a metal in contact with a solution of one of its own salts, e.g., copper in copper sulfate, zinc in zinc sulfate, etc. The two electrodes of a Daniell cell are of this type.

Electrodes of the Second Type, consisting of a metal in contact with a solution containing one of its difficultly soluble salts and a second soluble salt of some other metal, having the same anion. The difficultly soluble salt, called the "depolarizer," must be present in excess as solid. Such an electrode is mercury in contact with a solution of zinc sulfate containing mercurous sulfate in excess as solid; this is one of the electrodes of the Clark cell.

Reversible Gas Electrode. An electrode consisting of "platinum black" saturated with an atmosphere of hydrogen gas and dipping partially into a solution containing hydrogen ions is also a reversible electrode. This is a special form of electrode of the first type in which a gas by being occluded in platinum is made to play the rôle of a metal. Other "gas electrodes," e.g., chlorine, may be similarly prepared.

10. CONTACT POTENTIALS; ELECTROMOTIVE FORCE

The electromotive force of a voltaic cell, the back-electromotive force of an electrolytic cell, and the electromotive force of a thermocouple are all due to differences of potential which always exist at the junction of dissimilar substances. For a general discussion of this subject, see Langmuir, *Trans. Am. Electrochem. Soc.*, 29, 125 (1916); Bridgman, *Phys. Rev.*, 14, 306 (1919); and Sommerfeld and Bethe, Handbuch der Physik, vol. 24, pp. 333–622 (Springer, Berlin, 1933).

THE VOLTA EFFECT. When pieces of two different metals are brought into metallic contact, it is found that between points in the surrounding medium (gas or vacuum) immediately outside the two metals a difference of potential exists. When the surrounding medium is a perfect vacuum, the potential difference is known as the true Volta contact potential difference between the metals in question. The Volta contact potential difference K_{AB} may be thought of as made up of three parts: the potential difference between the ether and A, the potential difference at the junction of the metals A and B, and the potential difference between B and the ether.

Investigations on the thermo- and photo-emission of electrons have demonstrated that an amount of work w_A is required to expel an electron from the metal A; from measurements on the thermo- and photo-emission of electrons from A and B the Volta contact potential difference between A and B may be obtained. K_{AB} may also be measured directly by the condenser method. Considerable difficulty has been experienced in the experimental determination of K_{AB}, due chiefly to the fact that the adsorption of minute traces of chemically active gases upon the surface of the metals greatly affects the results. The following table, taken from the International Critical Tables, vol. 6, p. 57, gives values of K_{AB} for a number of pairs of conductors.

Table 2. Contact Potential of Miscellaneous Pairs of Conductors, Condenser Method, Room Temperature

$K_{AB} = V_A - V_B$, unit = 1 volt.

* In vacuum. † Fresh surface. ‡ Old surface. § Initial value in dry air, pressure 0.05 mm. Hg. K_{AB} varies with the time. ¶ Coconut charcoal saturated with the gas indicated.

THE PELTIER EFFECT. Heat is absorbed or evolved when a current passes though the junction of two metals, and reversal of the current causes the reversal of the heat effect. Conversely, if the two junctions of a closed circuit composed of metals A and B in series are kept at different temperatures, current flows around the circuit. Let the metals be so designated that current flows from A to B at the hot junction, and let P_{AB} be the heat absorbed when unit quantity of positive electricity flows from A to B at the temperature T. It may be shown thermodynamically that the temperature coefficient of the emf of the circuit is related to the Peltier heat P_{AB} by the equation

$$T\frac{dE_{AB}}{dT} = P_{AB}$$

where the subscripts indicate the direction of flow of the current at the hot junction.

P_{AB} is also known as the Peltier coefficient and as the Peltier electromotive force. The use of the term "Peltier emf," with the understanding that the heat absorbed is equal to the emf located at the junction between the metals, is open to criticism; see Bridgman, *Phys. Rev.*, 14, 318 (1919).

Numerous data for the computation of the Peltier heat and the thermoelectric emf of a bimetallic circuit are to be found in the International Critical Tables, vol. 6, pp. 213–229. For most pairs of metals P_{AB} is of the order of magnitude of a few millivolts; in the case of antimony and bismuth, however, it is approximately 0.03 volt. Fair agreement exists between the values of P_{AB} directly observed and the values computed from the equation

$$P_{AB} = T\frac{dE_{AB}}{dT}.$$

LIQUID-LIQUID POTENTIALS. When two dissimilar electrolytic solutions are brought into contact the phenomenon of diffusion takes place between them until a homogeneous mixture results. At the same time a difference of potential is produced between the solutions, the magnitude of which depends upon the velocity of migration and the relative concentration of the ions taking part in the diffusion, the charge which they carry, the absolute temperature, and the gas constant. Liquid junction potentials like metal-metal potentials are, in general, of small magnitude. Thus the potential difference between two solutions of potassium chloride, one solution having 10 times the concentration of the other, is only 0.0005 volt, and diminishes as the ratio of the concentrations approaches unity. Potassium chloride is often used as an intermediate electrolyte when it is desired to reduce the liquid-liquid potentials of a voltaic combination to a minimum because of the small potential to which it gives rise.

Liquid potentials are greatest between acid or between alkali solutions. Thus, between two hydrochloric acid solutions whose concentrations are in the ratio 10 to 1 at a temperature of 18 deg cent there is a potential difference of about 0.038 volt; between two sodium-hydrate solutions under the same conditions there is a potential difference of 0.034 volt.

METAL-LIQUID POTENTIALS. From what has been said regarding the magnitude of metal-metal and liquid-liquid potentials, it follows by the process of elimination that the main seat of the electromotive force of a voltaic cell must reside at the junctions between metals and liquids. The determination of the *absolute* value of the potential difference between a metal and the solution with which it is in contact is problematical. In practice electrode potentials are stated relative to that of the normal hydrogen electrode, which is by definition zero. Two normal electrodes are in common use, namely, the calomel electrode and the hydrogen electrode.

NORMAL CALOMEL ELECTRODE. The normal calomel electrode consists of mercury in contact with a normal solution of potassium chloride saturated with mercurous chloride, the latter being present in excess as a solid.

NORMAL HYDROGEN ELECTRODE. The normal hydrogen electrode consists of a strip of platinum coated with a thin deposit of platinum black and saturated with hydrogen gas at atmospheric pressure. The electrode is mounted partially surrounded by hydrogen gas and partly dipping into an acid solution in which the activity of the hydrogen ion (see below) is unity.

From a normal hydrogen to a normal calomel electrode at 25 deg cent there is a rise of potential (corrected for the liquid junction potential) of 0.281 volt, hence, if from a hydrogen electrode to any metal electrode the rise of potential is e_h, and if from a calomel electrode to any metal electrode the rise of potential is e_c, then

$$e_h = e_c + 0.281 \text{ volt}$$

The difference between any two metal-liquid potentials remains the same irrespective of the normal electrode to which they are referred.

SPECIFIC ELECTRODE POTENTIALS. Table 3, in which most of the values are taken from The International Critical Tables, vol. 6, p. 332, gives the potential drop at an electrode dipping into a solution in which the molal activity (see below) of the ions in equilibrium with the electrode is unity. "All molecular and ion species whose concentrations are not fixed by the nature of the phases present as shown by the reaction given are at the concentration at which their molal activities are unity, the activity coefficients being those given by Lewis and Randall (Thermodynamics and the Free Energy of Chemical Substances, New York, McGraw-Hill, 1923), except for HCl, for which see Randall and Young, *J. Am. Chem. Soc.*, 50, 989 (1928). All gases are present at a pressure of one atmosphere."

The electromotive force of a cell (with liquid junction potentials eliminated) is equal to the algebraic difference of the specific electrode potentials involved.

Table 3. Electrodes in Equilibrium with Aqueous Solutions in Which the Molal Activity of the Ions Indicated is Unity. The Electrode Assumes a Charge against the Solution of the Sign and Magnitude Indicated. T = 25 deg cent

Electrochemical Reaction	Volts	Electrochemical Reaction	Volts
$Li - (-) = Li^+$	−2.96	$2H^+ + 2(-) = H_2$	0.0
$K - (-) = K^+$	−2.92	$Cu^{++} + 2(-) = Cu$	+0.34
$Na - (-) = Na^+$	−2.72	$O_2 + 2H_2O + 4(-) = 4OH^-$	+0.41
$Mg - 2(-) = Mg^{++}$	−1.55	$I_2 + 2(-) = 2I^-$	+0.54

$Co - 2(-) = Co^{++}$	−0.29	$Br_2 + 2(-) = 2Br^-$	+1.07
$Ni - 2(-) = Ni^{++}$	−0.23	$Cl_2 + 2(-) = 2Cl^-$	+1.36
$Sn - 2(-) = Sn^{++}$	−0.14	$Au^{+++} + 3(-) = Au$	+1.36
$Pb - 2(-) = Pb^{++}$	−0.12	$F_2 + 2(-) = 2F^-$	+1.9
$Fe - 3(-) = Fe^{+++}$	−0.04		
$H_2 - 2(-) = 2H^+$	±0.0		

Since the evaluation of individual ion activities involves the adoption of an arbitrary convention, specific electrode potentials are to be regarded as somewhat arbitrary.

VARIATION OF ELECTRODE POTENTIALS WITH CONCENTRATION. The change in the value of an electrode potential with change in the concentration of the ion with which the electrode is in equilibrium is given by the formula

$$e_1 - e_2 = 0.000198T/n \log_{10} a_1/a_2$$

$$e_1 - e_2 = 0.000198T/n \log_{10} m_1 \gamma_1/m_2\gamma_2$$

where e_1 is the electrode potential at concentration m_1, e_2 at concentration m_2, T the absolute temperature, n the valence of the ion, and $m_1\gamma_1 = a_1$, the activity of the ion (see below) at concentration m_1. The activity coefficient γ expresses the deviation from the gas laws; if γ is the same for solutions 1 and 2, the change in electrode potential may be obtained directly from the ratio of concentrations.

ELECTROCHEMICAL SERIES—NOBILITY OF THE ELEMENTS. The elements, as arranged in Table 3, constitute the "electrochemical series." Those elements for which e_h is negative are said to be less "noble" than hydrogen; those for which e_h is positive are said to be more "noble" than hydrogen. The alkali metals having the greatest tendency to form ions in water stand at one end while the "noble" metals, such as gold, platinum, palladium, having but a very slight tendency to form ions, are

at the other end. The halogens which go into solution as negative instead of positive ions stand at the lower end of the series. Other series have been given which differ from the above in that the elements are not compared under similar conditions in regard to the concentration of the solution with which they are in contact. Changing the electrolyte, e.g., to potassium cyanide, not only alters the numerical values of the potentials, but may completely change the order in which certain elements occur in the series.

Any metal if placed in a solution of a salt of a metal standing below it in the series will tend to replace it; thus, zinc precipitates iron, copper, silver, etc., from their solutions but will not displace the alkali metals from solutions of their salts. Any metal standing above hydrogen will tend to displace it from an acid solution with evolution of hydrogen. Metals below hydrogen in the series will not dissolve in acid by a simple replacement of hydrogen. From a chemical standpoint the adoption of the hydrogen electrode as a standard has the advantage over the calomel standard that it divides the metals into two groups according to their behavior towards acids.

The approximate electromotive force of a battery consisting of two metals dipping into normal solutions of their respective salts may also be computed at once from the table by taking the difference of the two corresponding electrode potentials. Thus a zinc-copper cell should have an electromotive force equal approximately to $E_{zn-cu} = (e_h)_{zn} - (e_h)_{cu} = -0.76 - 0.34 = -1.10$, the rise of potential being from the zinc to the copper in the cell. As a matter of fact, this combination, the Daniell cell, has an electromotive force of approximately 1.10 volts. Other conclusions to be drawn from the table will be pointed out below.

11. ELECTROMOTIVE FORCE AND HEAT OF REACTION

The electromotive force of a reversible cell maintained at constant temperature may be readily calculated from the first and second law of thermodynamics. By a "reversible" cell is meant a cell which does not polarize and which operates under conditions such that changes which take place within the cell constitute a thermodynamically reversible process. The discussion given below also applies, with a rough degree of approximation, to most commercial cells, which, as a rule, are not strictly reversible.

GIBBS-HELMHOLTZ EQUATION. In the case of a reversible cell, such, for example, as the Daniell cell,* shown in Fig. 1, the relation between the heat of reaction and the electromotive force of the cell is calculated as follows.

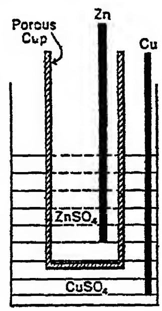

FIG. 1. Daniell Cell

From Faraday's laws, the quantity of electricity which must flow through the cell in order to deposit or liberate one gram-ion at either electrode is nF coulombs, where n is the valence of the ion of highest valence involved in the chemical reaction and F is the electrochemical constant (see above). Hence, the external work done by the cell (when there is no other external work than electrical work) is nFE joules, where E is the emf of the cell. If the cell is kept at the same temperature (T degrees, absolute scale) as the surrounding bodies, then the external work nFE done by the cell is the maximum external work it can do at this temperature T (see Vol. 1, Thermodynamics). Hence,

$$nFE = H' + nFT\frac{dE}{dT}$$

or

$$E = \frac{H'}{nF} + T\frac{dE}{dT}$$

where H' = the heat of reaction (heat evolved) in joules per gram-ion, corresponding to the chemical change which takes place.† H gives the change in intrinsic energy corresponding to the chemical changes which take place within the cell. This can be found by an independent calorimetric measurement, by causing the reaction to take place under such conditions (*constant volume*) that heat is the only form of energy produced.

TEMPERATURE COEFFICIENT OF ELECTROMOTIVE FORCE. From the above equation it follows that the energy developed by the cell is equal to the heat energy of the chemical reaction taking place within it plus a certain other quantity of energy equal

* The special construction of this cell renders it reversible.

† Since 1 large mean calorie (Ostwald calorie) = 418.5 joules and F = 96,500, this may be written, putting H = heat of reaction in large mean calories,

$$E = \frac{H}{2.036n} + T\frac{dE}{dT}$$

to $nFT\,dE/dT$. This may be either positive or negative, according as the temperature coefficient of electromotive force dE/dT is plus or minus, i.e., according as the electromotive force of the cell increases or decreases with the temperature. If the electromotive force on open circuit increases with the temperature of the cell, then on closed circuit the cell will tend to cool, i.e., its temperature will fall, and its electromotive force will likewise decrease, the energy $nFT\,dE/dT$ being derived from the heat energy within the cell (or surroundings). If the electromotive force on open circuit decreases with increasing temperature of the cell, then on closed circuit the cell will tend to heat up, i.e., its temperature will rise and its electromotive force will decrease. A cell for which dE/dT is other than zero can work at constant temperature only by absorbing heat from or giving out heat to the surroundings.

Only for the unique conditions that $dE/dT = 0$, or that $T = 0$, i.e., when the electromotive force is independent of the temperature or the cell works at temperatures approaching absolute zero, is $E = H'/nF$. By a curious chance it happens that the first of these conditions practically obtains in the Daniell cell considered above. The electromotive force of the cell is nearly independent of the temperature. Its observed value is $E = 1.10$ volts, while its value computed by the above equation, putting $dE/dT = 0$, is 1.09 volts.

THOMSON'S RULE. In computing the electromotive force of a battery from heats of reaction it is usually necessary to content oneself with a first approximation and neglect the second term in the above equation, since at present few data are available from which the value of dE/dT can, a priori, be obtained. The approximate equation

$$E = \frac{H'}{nF} = \frac{H}{230.6n}$$

is known as Thomson's rule. (H' is in joules, H in large mean calories.)

This rule also applies approximately to most commercial cells, although these are not strictly reversible. Of course, the heat of reaction used must be that corresponding to the actual chemical changes which take place in the cell.

NERNST'S THERMODYNAMIC THEOREM. Nernst, by assuming that the values of the intrinsic energy and free energy of a system not only become equal at the absolute zero but also that they approach equality asymptotically at this point, has been able to express the electromotive force (E) of a cell explicitly in terms of the thermal properties of the substances taking place in the reaction. So far as the new formula has been tested a satisfactory agreement has been found between theory and experiment. The principles involved are of fundamental importance and are fully discussed in Nernst's Silliman Lectures, Applications of Thermodynamics to Chemistry. See also Nernst's Theoretical Chemistry and Lewis and Randall's Thermodynamics, Chapter 31.

CONCENTRATION CELLS. Concentration cells may be divided into two classes: (*a*) those without liquid junction (without transference), and (*b*) those with liquid junction (with transference).

As an illustration of the former class the cell

$$\mathrm{Ag, AgCl} \mid \mathrm{HCl}(m_2) \mid \mathrm{H_2} \mid \mathrm{HCl}(m_1) \mid \mathrm{AgCl, Ag}$$

will serve. Here m_2 represents the concentration of hydrochloric acid in the more concentrated solution, m_1 the concentration of acid in the more dilute solution. The cell reaction is

$$\mathrm{HCl}(m_2) \rightarrow \mathrm{HCl}(m_1)$$

and if $\bar{F}_2$ and $\bar{F}_1$ are the partial molal free energies of hydrochloric acid in the two solutions the electromotive force of the cell is

$$E = (\bar{F}_2 - \bar{F}_1)/F$$

As an illustration of the latter class, the cell

$$\mathrm{Ag, AgCl} \mid \mathrm{HCl}(m_2), \mathrm{HCl}(m_1) \mid \mathrm{AgCl, Ag}$$

will serve. Let us suppose that to the left of the point A in the solution the concentration of the acid is constant and equal to m_2, and to the right of the point B, the concentration of the acid is constant and equal to m_1. Between the two points the concentration varies continuously. Then the electromotive force of the cell is given by the equation

$$E = -1/F\int_A^B t^+\,d\bar{F}$$

where t^+ is the transference number of the cation and $\bar{F}$ is the partial molal free energy of the acid. For a discussion of the general case, see Taylor, *J. Phys. Chem.*, 31, 1478 (1927). See also MacInnes and Beattie, *J. Am. Chem. Soc.*, 42, 1117 (1920), for the application of this method to the determination of transference numbers.

CARBON GENERATOR. The problem of converting the energy liberated in the combustion of carbon to carbon dioxide directly into electric energy has not yet been practically solved. The reaction, $C + O_2 = CO_2$, liberates a very large quantity of heat, namely, 961 large calories per gram-atom of carbon consumed. Of this, only about 10 per cent is converted into electrical energy through the agency of a steam engine and dynamo. The difficulties encountered in devising a commercial carbon generator are the following: (1) the velocity of the above reaction is small, except at high temperatures; (2) it is difficult to utilize a gas as an electrode, except through the agency of a conducting medium which occludes it, such as platinum black; (3) a satisfactory high-temperature electrolyte which will not deteriorate in the presence of CO_2 is difficult to obtain; and (4) carbon has a slight tendency to form ions.

12. ELECTROLYTIC DECOMPOSITION

Faraday's laws enable one to determine the amount of the substances primarily liberated or deposited at the electrodes of any electrolytic cell, but they do not enable one to predict the nature of the secondary chemical actions which may take place. The factors which determine what products will be formed in any given case are numerous. The chemical process occurring at the cathode is always of the nature of a reduction; at the anode, of an oxidation, these terms being used in their most general sense. It may be that the electrolyte, taken as a whole, undergoes no change, as is the case, for example, of a copper-sulfate solution when electrolyzed between copper electrodes. Here the chemical reaction at the cathode is the exact reverse of that at the anode. Generally, however, this is not the case; different chemical products are usually formed at the two electrodes, and appear either in the form of gas or as a solid precipitate, or remain dissolved in the electrolyte.

DECOMPOSITION VOLTAGE OF ELECTROLYTES. When a gradually increasing difference of potential is applied to the electrodes of an electrolytic cell, electrolysis does not in general begin at once but only after a certain minimum electromotive force is reached, even though the cell has no open-circuit emf. It should be noted that this condition does not apply to the case when the electrodes are such that the electrolyte as a whole undergoes no change as a result of electrolysis. The minimum voltage necessary to decompose a compound electrolytically is called its "decomposition voltage." It is influenced by a variety of factors and conditions.

Dilute solutions of most acids and bases have approximately the same decomposition voltage; this is due to the fact that it is the ions of water which are discharged at the electrodes. Salt solutions show considerable variation in decomposition voltage.

MEASUREMENT OF DECOMPOSITION VOLTAGE. Decomposition voltages have been experimentally determined in several ways. Certain investigators have taken the value necessary to produce visible electrolysis as the criterion; others have followed the polarization at the electrodes until it became constant and assumed this value as that at which electrolysis begins. Results obtained by the so-called ammeter-voltmeter method must be accepted with caution. In this method the value of the electromotive force applied to the cell is gradually increased from zero and plotted as abscissas and the corresponding currents through the cell plotted as ordinates. The resulting curves have the general form shown in Fig. 2.

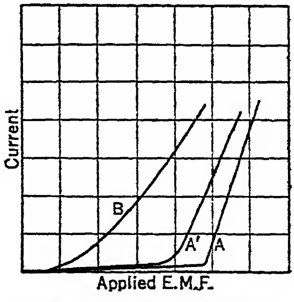

FIG. 2. Conductivity of Electrolytic Cells

The slope of these current-voltage curves depends upon the internal resistance of the cell, the size and the distance apart of electrodes. The critical voltage at which the current suddenly increases in value is, however, quite sharply defined with some electrolytes, e.g., silver nitrate between platinum electrodes, and other salts from which a metal is deposited. Below the critical voltage very little or no current passes through the cell and no visible decomposition at the electrodes is apparent. When the point A is reached, visible electrolysis begins. The sharpness of the bend in the curve and its course below A depend in large measure upon the sensitiveness of the galvanometer used for detecting the current, the size of electrodes and the tendency of the products of the electrolysis to go back into solution.

RESIDUAL CURRENTS. With a sensitive reflecting galvanometer, a steady deflection may be observed for days without any apparent electrolysis when an emf of a few

tenths of a volt (far below the " decomposition voltage ") is applied to platinum electrodes dipping into acidulated water. It might seem from this that Faraday's law is here violated. These slight currents are to be explained, however, by a diffusion of the products liberated slowly and in minute quantities at the electrodes, back into the solution. Currents produced in this manner are called " residual currents " and play an important rôle in the electrolysis of fused salts and probably also in conduction in solid electrolytes. The larger the residual current the less sharply marked is the decomposition point, see A'. For many fused salts the current-voltage curve is of the form shown in B, Fig. 2. It would be difficult to say from this curve at what voltage decomposition actually began.

OVERVOLTAGE. When a gas is evolved at either electrode the above relations are usually more complicated owing to the phenomenon known as overvoltage. Thus in the electrolysis of an acid between polished platinum or other metal electrodes, hydrogen gas is evolved, to liberate which the cathode potential must be raised to a value in excess of that required to liberate hydrogen at a reversible (platinum black) electrode.

This excess of voltage which is necessary to liberate a gas at any electrode over that required to liberate the same gas against a *reversible* gas electrode is called " overvoltage."

Its value depends on the character of the material of the electrode against which the gas is set free, upon the nature of the gas, and upon the current density employed. Moreover, the value obtained depends to a considerable extent upon the method of measurement used. In the earlier work on overvoltage a continuous current was employed; see Caspari, *Z. physik. Chem.*, 30, 89 (1899); Müller, *ibid.*, 50, 641 (1905); Tafel, *ibid.*, 65, 226 (1909). Most of the recent work has been done using an intermittent current; see Newbery, *J. Chem. Soc.*, 109, 1051, 1066 (1916); Glasstone, *ibid.*, 123, 1745 (1923); Knobel, *J. Am. Chem. Soc.*, 46, 2613, 2751 (1924). The overvoltages obtained by the former method are higher than those obtained by the latter.

Varying conditions make the usual reproducibility of overvoltage determinations not better than 0.05 volt. For tables showing the overvoltages of hydrogen, oxygen, and the halogens against various metals see the International Critical Tables, vol. 6, p. 339.

A study of the change of oxygen and hydrogen overvoltage with time has been made by Bowden and Rideal (see Bowden and Rideal, *Proc. Roy. Soc.*, A120, 59 (1928); Bowden, *ibid.*, A125, 446 (1929), A126, 107 (1929); Bowden and O'Connor, *ibid.*, A128, 317 (1930)).

ELECTROLYTIC SEPARATION OF METALS. The reason that two or more metals can be electrolytically separated from each other by a regulation of voltage follows from the preceding discussion. Consider a solution containing two salts, say silver and copper nitrates, each at normal concentration. If a gradually increasing emf be applied to inert electrodes dipping into this solution, electrolysis will begin when a voltage is reached sufficient to set free *simultaneously* any anions and cations present in the solution. Referring to Table 3, it will be seen that copper stands $0.80 - 0.34 = 0.46$ volt above silver in the electrochemical series, and hence silver can be deposited from the solution with emf nearly half a volt less than copper. No copper ions can separate until the applied emf has been increased 0.46 volt above that necessary to first separate the silver. The decomposition emf necessary will, of course, depend on the nature and concentration of the anions present. As electrolysis proceeds, the solution becomes weaker and weaker with respect to silver ions and the voltage necessary to separate them from the solution increases. If the electrolysis is continued until the silver remaining in solution has a concentration only 1/1,000,000 that at the start (the limit of analytical determinations), the change in voltage will be approximately 0.35 volt (see section above on Variation of Electrode Potentials with Concentration). This is still insufficient to bring the applied emf up to a value sufficient to permit the copper to deposit, and hence, for all practical purposes, silver and copper may be completely separated from each other. This process may be greatly accelerated by violently stirring the solution, as, for example, by the use of a rapidly rotating electrode.

ELECTRODE REACTIONS. Below are listed a number of reactions, of various types, by which the current is conducted from the solution to the electrode, or vice versa. The ultimate products are often quite different from the ions which conduct the current through the solution.

At the cathode:

$$2H^+ + 2(-) \rightarrow H_2$$

$$Cu^{++} + 2(-) \rightarrow Cu$$

$$8H^+ + 2SO_4^{--} + 2(-) \rightarrow SO_3^{--} + S + 5H_2O$$

$$Ag(CN)_2^- + (-) \rightarrow Ag + 2CN^-$$

$$4H^+ + PbO_2 + 4(-) \rightarrow Pb + 2H_2O$$

At the anode:

$$2Cl^- \rightarrow Cl_2 + 2(-)$$
$$4OH^- \rightarrow 2H_2O + O_2 + 4(-)$$
$$\begin{array}{l} COO^- \\ | \qquad \rightarrow 2CO_2 + 2(-) \\ COO^- \end{array}$$
$$2CH_3COO^- \rightarrow 2CO_2 + C_2H_6 + 2(-)$$

Which reaction is most likely to occur in any given case depends to some extent upon (a) current density, (b) temperature, (c) concentration of the solution, as well as upon the electrode potential.

In general, it may be said that at the cathode a reduction takes place, while at the anode oxidation (in its general sense) occurs. The intensity of these reactions depends upon the electrode potential at which the reaction takes place. This can be varied by the use of different electrode materials (thereby increasing the overvoltage). The efficiency of certain secondary reactions has also been found to depend upon the nature of the electrode (catalytic action). The efficacy of electrolytic reduction and oxidation in organic chemistry where the intensity of the reaction must be carefully regulated likewise rests on the above factors.

PASSIVITY. A metal is said to assume the "passive" state when it comports itself towards acids like a noble metal, i.e., becomes insoluble. Iron affords a very striking example of this phenomenon, although it is exhibited by other metals as well. Thus, if dipped in strong nitric acid, or if anodically polarized, it becomes passive. Several theories have been advanced to account for the phenomenon, but it is at present generally accepted that passivity is caused by the presence of a thin, insoluble film on the surface of the metal. It has been possible to isolate the film in some cases. For a review of the field see Desch, The Chemistry of Solids, Chapter 7 (Cornell Univ. Press). For résumé of theories see *Trans. Am. Elec. Chem. Soc.*, 29, 217 (1916); and see also the section on passivity in Foerster's Electrochemie wässeriger Losungen, Barth, Leipzig, 1921.

ALTERNATING-CURRENT ELECTROLYSIS. The decomposition of an electrolyte, and the solution of metal electrodes by electrolysis, can be effected under certain conditions by an alternating current as well as by a direct current. The chief determining factors are the velocity with which the chemical reaction takes place and the periodicity of the alternating current.

13. THEORY OF SOLUTIONS

To understand the theory of the various phenomena described above, a knowledge of the theory of solutions is necessary. Progress has been made in this field so rapidly that much of the material presented in textbooks is out of date. The following paragraphs will attempt to sketch the important advances.

SOLUTIONS OF NON-ELECTROLYTES. From the work of Raoult on the depression of the freezing point, the elevation of the boiling point, and the lowering of the vapor pressure of solutions, the general law was deduced that for a binary system

$$p_A = p_{A0} N_A$$

where p_{A0} represents the vapor pressure of pure solvent A and p_A its vapor pressure when present in a solution in which its mol fraction is N_A.

The law of Henry, as originally stated in 1803 is

$$c/p = k$$

where c is the concentration of the volatile solute, p its partial pressure, and k a constant characteristic of the substance. In terms of mol fractions this becomes

$$p_B = k'N_B$$

The third law found applicable to solutions of non-electrolytes is van't Hoff's law of osmotic pressure (1888).

OSMOTIC PRESSURE. The earliest recorded observations of the process of osmosis seem to have been those of Abbé Nollet in 1748, who found that, if a glass vessel was filled with alcohol, the opening covered with a bladder, and the vessel immersed in water, the bladder expanded and burst. In terms of a semi-permeable membrane the osmotic pressure may be defined as the equivalent of hydrostatic pressure produced when the solution and solvent, separated by a membrane permeable to the solvent, are in equilibrium, or as the equivalent of the excess pressure which must be imposed on a solution to prevent the passage into it of solvent through a semi-permeable membrane.

SEMI-PERMEABLE MEMBRANES. If a solution be placed at the bottom of a cylinder and carefully covered with a layer of pure solvent, the process of diffusion will begin at once and continue until a homogeneous dilute solution is formed. If the experiment be repeated with the single modification, that the pure solvent is separated from the solution by a piston consisting of a semi-permeable diaphragm which will permit the solvent to pass freely through it in either direction, but which will not allow the solute to pass through, the process of diffusion will take place as before, provided the piston is movable. Thus the piston will be forced back by the osmotic pressure of the solution while the solvent passes freely through it, thereby diluting the solution. Membranes possessing the property of semi-permeability are not only theoretically conceivable but may actually be prepared. Such a membrane is formed by the precipitate of copper ferrocyanide deposited within the walls of an unglazed porous cell when copper sulfate and potassium ferrocyanide solutions are allowed to diffuse into the cell from within and without respectively. This membrane is permeable to water, but impermeable to sugar and many other organic and inorganic substances, such as the copper and potassium salts from which it is formed. Most membranes, in fact, possess the property of semi-permeability to a limited degree.

MEASUREMENT OF OSMOTIC PRESSURE. To prevent the piston being forced up by the diffusing solution, a downward pressure P must be applied to it equal to that exerted upon it from below by the solution. The magnitude of P is, therefore, a measure of the osmotic pressure of the solution. Owing to experimental difficulties, it is impracticable to measure osmotic pressures in precisely the manner just described, but by slightly modifying the arrangement of the apparatus it may readily be done. Thus, if the solution is contained in a closed vessel, A, Fig. 3, the walls of which are made semipermeable by depositing a membrane of copper ferrocyanide within the pores of the cell, and this be immersed in the solvent B, the osmotic pressure will be exerted as before against the membrane from within. If the membrane could stretch like a rubber balloon, it would do so as the solution became diluted; but as it is restrained from doing this by the material of the walls of the cell on and in which it is deposited, dilution of the solution can take place by the solvent passing through the fixed membrane into the solution cell. This it will do unless the cell A is hermetically sealed. If an open manometer M of small bore be inserted in the top of A, the solvent as it passes into the cell will cause the solution to rise gradually in M until the hydrostatic pressure thus produced prevents further entrance of solvent. When equilibrium is established, the hydrostatic pressure gives a measure of the osmotic pressure of the solution then existing in the cell. As the entrance of an appreciable amount of solvent into the cell reduces the concentration of the solution, the pressure thus measured is less than that of the original solution; hence for quantitative work an open manometer is replaced by a closed mercury manometer.

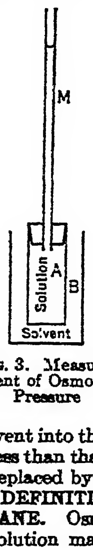

FIG. 3. Measurement of Osmotic Pressure

DEFINITION OF OSMOTIC PRESSURE WITHOUT REFERENCE TO A MEMBRANE. Osmotic pressure can also be defined in the following way. Let us consider a solution made up of the substance A and any number of other components. In a second vessel we have pure A. The partial pressure of A from the solution is less than from pure A at the same temperature, so that A would tend to distil from the pure substance into the solution. Distillation could be prevented by increasing the external pressure on the solution until the partial pressure of A from the solution was equal to that of pure A, or by decreasing the external pressure on the pure A until the vapor pressures were equal. The difference in total pressure on the two vessels is called the osmotic pressure.

The effect of external pressure on vapor pressure was first formulated by Poynting in 1881, and for dilute solutions is given by the equation

$$dp/dP = V_0/v$$

where P is the total applied pressure, p the vapor pressure of the solvent, V_0 the volume of one gram-molecule of solvent in the liquid state, and v the volume of one gram-molecule of solvent in the gaseous state. If $d\pi$ is the change in osmotic pressure corresponding to a change dp in the vapor pressure of the solvent, since $d\pi = -dP$

$$dp/d\pi = -V_0/v \quad \pi = (RT/V_0)\ln p_{A0}/p_A$$

Recently a new method of measuring osmotic pressure based upon the principles above has been devised; see Townsend, *J. Am. Chem. Soc.*, 50, 2958 (1928).

LAWS OF OSMOTIC PRESSURE IN NON-ELECTROLYTIC SOLUTIONS. The following laws were established by the early experiments on the osmotic pressure of dilute aqueous solutions of many organic substances, and of many solutions of non-electrolytes in organic solvents. These laws were the basis of van't Hoff's reasoning that the osmotic pressure of a solution was due to the impacts of the solute molecules on the semi-permeable membrane, the impacts of the solvent molecules being the same on both sides.

1. The osmotic pressure of a solution is directly proportional to its concentration (and therefore inversely proportional to the volume in which a given mass of the solute is dissolved).
2. It is directly proportional to the absolute temperature.
3. It is independent of the nature of the solute, being a function solely of the number of mols of substance dissolved in unit volume of solution.
4. The numerical magnitude of the osmotic pressure π of one mol of any substance dissolved in a volume v of solution at the absolute temperature T is identical with the gaseous pressure exerted by one mol of a perfect gas at the temperature T and occupying the same volume v.

The gas laws are therefore not only directly applicable to solutions, but the numerical value of the gas constant R is the same for each. Thus the combined laws of Boyle and Gay-Lussac for gases have the same form for solutions, namely,

$$\pi v = RT$$

where π = the osmotic pressure, v = the volume of the solution containing one mol of solute, and T = the absolute temperature.

Concentrated solutions of non-electrolytes deviate from these laws, just as highly compressed gases deviate from the gas laws.

THE LAWS OF DILUTE SOLUTION. DEVIATIONS THEREFROM. ACTIVITY. On the assumption that the vapors of solvent and solute obey the gas laws, any two of the following laws—Raoult's, Henry's, van't Hoff's—may be derived from the third. This may be done by means of Carnot cycles, or by the general principles and formulas of Gibbs; see Guggenheim, *J. Phys. Chem.*, 34, 1751 (1930).

Actual solutions of finite concentration show deviations from these ideal laws. In order to express the deviation Lewis introduced the idea of activity. He defined activity by the equation

$$\bar{F} = RT \ln a + B$$

where $\bar{F}$ is the partial molal free energy of the component in question, a its relative activity, and B, for a given solute and solvent, is a constant dependent on the temperature and pressure. In terms of this definition Raoult's law becomes

$$a_A = N_A$$

The activity can be determined from vapor pressure measurements, electromotive force measurements, etc. See Lewis and Randall, Thermodynamics.

SOLUTIONS OF ELECTROLYTES. THE THEORY OF ELECTROLYTIC DISSOCIATION. Arrhenius studied the conductivities of a large number of acids, bases, and salts in aqueous solution and noted that the specific conductivity did not vary directly with the concentration. When the data of Raoult on the lowering of the freezing point were published, Arrhenius put forward the theory of electrolytic dissociation. See Arrhenius, *Z. physik. Chem.*, 1, 631 (1887). He showed that α, the degree of dissociation of the electrolyte, calculated from the ratio of conductivities

$$\alpha = \Lambda/\Lambda_0$$

where Λ is the equivalent conductivity of the solution in question, Λ_0 the equivalent conductivity of an infinitely dilute solution, could be explained on the basis that salts, acids, and bases of the type RX dissociated into ions

$$RX \rightleftharpoons R^+ + X^-$$

He showed that i calculated from the equation $\pi v = iRT$ and from the lowering of the freezing point ($i = \Delta T/1.85$) could be related to α by the equation

$$i = 1 + (k - 1)\alpha$$

where k is the number of ions formed from each molecule.

Ostwald showed that the dissociation of weak monobasic acids in aqueous solution followed the mass law,

$$\alpha^2/(1 - \alpha)v = k$$

where α is the degree of dissociation and v the reciprocal of the total concentration.

It is to be noted in what follows that the experimental basis and subsequent support

of the idea of electrolytic dissociation were largely confined to work in aqueous solutions. The arguments in favor of electrolytic dissociation may be summarized as follows:

(1) Solutions of electrolytes show two independent sets of chemical properties, as if there were two independent constituents present. This fact is of course exceedingly important in analytical chemistry, particularly in qualitative analysis. Related to this is the fact that the heat of neutralization of a strong acid by a strong base, in dilute solution, is constant.

(2) Certain physical properties of solutions (specific volume, density, color, index of refraction, etc.) are additive with respect to the ionic components. For instance, in a colorless solvent, solutions of salts with one colorless ion and a common colored ion show, at high dilution, the same absorption spectrum.

(3) Solutions of electrolytes conduct electricity, and the equivalent conductance increases with dilution but approaches a limiting value.

(4) The abnormally high freezing-point depressions, boiling-point elevations, and osmotic pressures of solutions of electrolytes are accounted for by the theory.

(5) Those acids which give the most highly conducting solutions are also the most active chemically, that is, they react upon metals the most rapidly, and they show the greatest catalytic effect in such reactions as the inversion of sucrose.

Lewis gives as the principal weaknesses of the theory (see Lewis, *Z. physik. Chem.*, 70, 212, 1910):

(1) Lack of agreement in some cases between values for the degree of dissociation calculated from freezing points on the one hand and from conductivities on the other. Thus, for $N/2$ LiCl, $MgCl_2$, and $Ca_2Fe(CN)_6$, the values of α from freezing-point data are 94, 99, and 2 per cent, respectively, while from conductivities they are 71, 62, and 20 per cent.

(2) Additivity of properties of ions is observed even when considerable quantities of undissociated molecules are supposed to be present.

(3) The most vulnerable point in the theory is what has been called "the anomaly of strong electrolytes." There is not the slightest tendency to follow the dilution law in dilute solutions of strong electrolytes. In non-aqueous solutions the law of mass action is still less applicable.

It is realized that in the case of many electrolytes the physical properties could be explained on the basis that there were practically no molecules of the electrolyte present in the solution. This will be discussed after the presentation of the section on electrolytic conduction.

14. THEORY OF ELECTROLYTIC CONDUCTION

The external effects of a current flowing through an electrolyte cannot be distinguished from those produced by a current of the same strength conducted by a metal. Thus the magnetic effect of a current flowing through a helical glass tube filled with electrolyte is the same as that produced by the same current flowing through an equivalent circuit of an equal number of turns of copper wire. A current may be induced in a closed ring of electrolyte just as in a ring of metal. Ohm's Law and Joule's Law hold for conduction in electrolytes as well as in metals. The mechanism of the conduction in the two cases, however, is very different, as shown by the phenomena produced at the junction of two conductors in one of which the conduction is metallic or "electronic" and in the other of which it is electrolytic or "ionic."

EQUIVALENT CONDUCTIVITY. When a solution containing one equivalent weight of electrolyte is placed between parallel electrodes 1 cm apart and is diluted with solvent, the conductivity increases as the volume of the solution increases. Table 4 shows the increase in equivalent conductivity with dilution for a number of electrolytes.

For electrolytes like KCl, NaCl, $AgNO_3$, i.e., for strong electrolytes, the value of the equivalent conductivity in infinitely dilute silution, Λ_0, is determined by extrapolation. Extrapolation is best made by means of the square root law of Kohlrausch

$$\Lambda = \Lambda_0 - a\sqrt{c}$$

i.e., the equivalent conductivity, plotted against the square root of the concentration, yields a straight line in dilute solution. This was established as an empirical rule by Kohlrausch; Onsager and Debye and Hückel have given it a theoretical basis.

That increase in the concentration should cause a decrease in conductivity appears reasonable enough; it might be thought of as due to incomplete ionization, or to increase in viscosity of the solution and consequent decrease in the speed of the ions, or to retardation of the ions because of electrical effects. Of course, a combination of causes might be operating.

Table 4. Equivalent Conductance Λ of Typical Electrolytes Dissolved in Different Quantities of Water, at 18 Deg Cent

Note.—The 1/2 before $CuSO_4$ and H_2SO_4 indicates 1 gram-equivalent = 1/2 mol.

For complete tables consult Landolt and Börnstein, Kohlrausch and Holborn, and Tables Annuelles Internationales de Constantes.

Because of the great increase of equivalent conductivity for electrolytes like NH_4OH and CH_3COOH when the solution is more dilute than 0.001 N, it is clear that, in order to obtain values of Λ from which to get Λ_0 by extrapolation, one would have to work with impossibly dilute solutions. The limiting value of the equivalent conductivity of a weak electrolyte is accordingly obtained in another way,

THE LAW OF INDEPENDENT MIGRATION OF IONS. Table 5 shows the limiting values of the equivalent conductivity for a series of potassium salts, and for a series of calcium salts, at 18 deg cent. The third and sixth columns of the table give the difference between the Λ_0 values of two salts with a common cation.

Table 5. Limiting Equivalent Conductivities of Some Salts of Potassium and Calcium

Salt	Λ_0	Difference	Salt	Λ_0	Difference
KCl.........	130.1		$CaCl_2$.........	116.5	
		− 1.5			− 1.5
KBr.........	131.6		$CaBr_2$.........	118.0	
		5.3			5.3
KNO_3........	126.3		$Ca(NO_3)_2$......	112.7	
		26.7			26.7
$KC_2H_3O_2$.....	99.6		$Ca(C_2H_3O_2)_2$...	86.0	
		1.1			1.1
KIO_3........	98.5		$Ca(IO_3)_2$.......	84.9	
		−34.1			−34.1
K_2SO_4.......	132.6		$CaSO_4$........	119.0	

Since the differences between the values of Λ_0 for KCl and KBr, and $CaCl_2$ and $CaBr_2$, are the same, although the individual values are quite different, Λ_0 must in each case be the sum of two constant quantities. That is to say, in infinitely dilute solution and at a given temperature, the current-carrying capacity of one equivalent of potassium ions is a fixed and constant quantity independent of the anion present. The limiting equivalent ionic conductance of the potassium ion is represented as l_{K^+}. The equivalent conductivity of an electrolyte at infinite dilution is equal to the sum of two constants, the equivalent conductances of anion and cation at infinite dilution,

$$\Lambda_0 = l_a + l_c$$

a law established by Kohlrausch and known as the law of the independent migration of ions.

This law immediately suggests a method of evaluating Λ_0 for electrolytes of the NH_4OH-CH_3COOH type, i.e., for weak electrolytes.

$$\Lambda_0 \text{ for } CH_3COOH = l_{H^+} + l_{CH_3COO^-}$$

$$\Lambda_0 \text{ for } CH_3COOH = \Lambda_0 \text{ for } HCl + \Lambda_0 \text{ for } CH_3COONa - \Lambda_0 \text{ for } NaCl.$$

From such a table of limiting equivalent conductivities as that given for the potassium and the calcium salts, it is evident that, if the absolute value of the limiting ionic conductance were known for one ion, all the other limiting ionic conductances might at once be calculated.

TRANSFERENCE NUMBERS OR TRANSPORT RATIOS. The current is carried through the solution by the simultaneous movement of the anions toward the anode, the cations toward the cathode. If the anions are faster moving than the cations, they carry the greater part of the current. For q coulombs of electricity passing, $q/96{,}500$ = number of equivalents of electricity passing = $N_t = N_a + N_c$, the number of equivalents carried by the anion, plus the number carried by the cation. The ratio N_a/N_t is called the transference number or the transport ratio of the anion, the ratio N_c/N_t is called the transference number or the transport ratio of the cation, in the solution in question. The sum of the transference numbers is unity.

The transference numbers are found from the changes in concentration which take place about the electrodes when a direct current is passed through the solution of an electrolyte. Consider the electrolysis of a solution of $AgNO_3$ between silver electrodes. When N_t equivalents of electricity have passed, N_t equivalents of silver have gone into the solution surrounding the anode, from the anode, and the same number of equivalents of silver have plated out from the solution surrounding the cathode, onto the cathode. N_c equivalents of silver have during this time moved out from the anode portion of the solution, and the same number have entered the cathode portion. The anode portion has gained $N_t - N_c$ equivalents of silver ion, and the cathode portion has lost the same number. The concentration of nitrate ion in the two portions has changed in the same

way. Analysis of either electrode portion, together with the coulometer reading, yields directly N_c/N_t, the transference number of the silver ion in a silver nitrate solution of the concentration given. For uni-univalent salts in solutions less concentrated than 0.01 N there is very little change in the transference numbers of the ions with change in concentration. Table 6 gives the transference numbers of the anions of a number of electrolytes in aqueous solution at 18 deg cent.

Transference numbers may also be evaluated by measurement of the electromotive force of concentration cells with transference (see for instance MacInnes and Parker, *J. Am. Chem. Soc.*, 37, 1445 (1915); and MacInnes and Beattie, *ibid.*, 42, 1117 (1920)), and by the moving boundary method (see MacInnes, Cowperthwaite, and Blanchard, *J. Am. Chem. Soc.*, 48, 1909 (1926); a review of the problem of the determination of transference numbers is given by MacInnes and Longsworth, *Chem. Reviews*, 11, 172 (1932). For a more complete table of transference numbers, and a comparison of the results obtained by the different methods, see the International Critical Tables, vol. 6, pp. 309–311.

LIMITING IONIC CONDUCTIVITIES. Since N_c/N_t represents the fraction of the current carried by the cation, $\Lambda N_c/N_t$ is the equivalent conductance of the cation. The limiting value of $\Lambda N_c/N_t$, that is to say, the conductance of one equivalent of the cation in an infinitely dilute solution, is l_c. From conductivity data, and from transference data, the tables of limiting equivalent ionic conductivities are built up. Table 7 gives values of the equivalent conductivities of some typical ions at infinite dilution and 18 deg cent.

Table 7. Conductivities of Typical Ions at Infinite Dilution and 18 Deg Cent

(Values at $t°$ may be computed by the formula $l_t = l_{18}[1 + \alpha(t - 18) + \beta(t - 18)^2]$) (Kohlrausch)

THE VELOCITY OF MIGRATION OF IONS. A charged body in an electric field is acted upon by a force equal to the product of the charge and the intensity of the field. If the field changes in one direction, only the force acting is

$$f = qdE/dx$$

where q is the charge of the particle, and dE/dx the gradient of the potential. The speed with which a small body moves through a medium of great frictional resistance is proportional to the force acting upon it. Therefore the speed u_c with which the cation moves through the solution is

$$u_c = kqdE/dx$$

The proportionality factor kq is written U_c and is the velocity of migration of the ion under unit potential gradient, or the *mobility*. Table 8 gives the velocity of migration of a number of ions.

The mobility of an ion of a given electrolyte is related very simply to the transference numbers, and to the equivalent conductivity (see Washburn, The Principles of Physical Chemistry, pp. 233–235). The former relationship is

$$N_c/(N_c + N_a) = U_c/U_c + U_a); \quad N_a/(N_c + N_a) = U_a/(U_c + U_a)$$

and the latter

$$\Lambda = F(U_c + U_a)$$

where F is the faraday.

THE CONDUCTANCE RATIO FOR STRONG AND FOR WEAK ELECTROLYTES. If the conductance ratio, Λ/Λ_0, is examined for a large number of strong and weak electrolytes, it is at once evident that the former class possess large values of the ratio Λ/Λ_0 as compared with the latter. For most uni-univalent salts, and for strong uni-univalent acids and bases, in aqueous solution, $\Lambda_{0.1\,N}/\Lambda_0$ is about 0.8. For bi-bivalent salts $\Lambda_{0.1\,N}/\Lambda_0$ is 0.4–0.5. Turning now to weak electrolytes, for NH_4OH and CH_3COOH in aqueous solution $\Lambda_{0.1\,N}/\Lambda_0 = 0.01$; for HClO and HCN, $\Lambda_{0.1\,N}/\Lambda_0 < 0.002$; and for the mercuric halides, $\Lambda_{0.1\,N}/\Lambda_0 < 0.001$.

In most textbooks at present in use the conductance ratios are regarded as measures of the degree of ionization, uni-univalent electrolytes of the KCl–$AgNO_3$ type (strong electrolytes) being said to be about 80 per cent ionized in 0.1 N solution. The weak electrolytes of the same valence type possess very much lower $\Lambda_{0.1\,N}/\Lambda_0$ values and are therefore considered much less ionized. There is far wider variation in the $\Lambda_{0.1\,N}/\Lambda_0$ ratio for weak electrolytes than for strong electrolytes of the same valence type. Examination of the ratio for a large number of uni-univalent salts shows that the deviation from the mean seldom exceeds 1 or 2 per cent, while changes in the conductance ratio for weak organic acids amount to hundreds of per cent.

It is obvious that the ratio $\Lambda_{0.1N}/\Lambda_0$ represents the degree of ionization of the electrolyte in 0.1 N solution only provided that in 0.1 N solution both ions move with the same speed as they do at infinite dilution.

Many of the Λ/Λ_0 ratios recorded in the literature are subjected to a viscosity correction. By Stokes's law, the speed with which a small particle moves through a medium of great frictional resistance is inversely proportional to the viscosity of the medium. Correcting for the effect of viscosity on the speed of the ions, the so-called " degree of ionization " becomes $\Lambda\eta/\Lambda_0\,\eta_0$ where η is the viscosity, rather than Λ/Λ_0.

APPLICATION OF THE MASS LAW TO STRONG AND TO WEAK ELECTROLYTES. There is another important difference in behavior between strong and weak electrolytes. For a uni-univalent electrolyte the dilution law of Ostwald (the law of mass action in terms of concentrations) runs

$$K_c = c_{A^+}c_{B^-}/c_{AB} = \alpha^2\,C/(1 - \alpha)$$

where α is the degree of ionization and C the stoichiometric concentration. This differs from the expression of the mass law by lack of the activity coefficient ratio, $f_{A^+}f_{B^-}/f_{AB}$. Now when α is represented by Λ/Λ_0 or, if there is a considerable change in the viscosity, by $\Lambda\eta/\Lambda_0\,\eta_0$, for weak electrolytes in aqueous solution fairly constant values are obtained for K_c. The classical example is perhaps acetic acid. As the concentration of acetic acid increases from 0.0001 to 1 M, K_c decreases from 1.87×10^{-5} to 1.74×10^{-5} (13 parts in 200, 7 per cent).

A strong electrolyte of the same valence type over the same concentration range

makes no pretense of obeying the dilution law. Nor does the inclusion of the ratio of activity coefficients

$$K_a = c_{A^+} c_{B^-} f_{A^+} f_{B^-} / c_{AB} f_{AB} = K_c f_{A^+} f_{B^-} / f_{AB}$$

yield a constant. Since the law of mass action is a thermodynamic law, it can only be concluded that the ratio Λ/Λ_0 does not represent with any accuracy the degree of ionization of strong electrolytes.

MODERN THEORIES OF SOLUTION. van Laar (*Arch. Teyler* (2) 7, I, 1 (1900)), Sutherland (*Phil. Mag.*, 14, 1 (1907)), and Bjerrum (*Z. Elektrochem.*, 24, 231 (1918)), from different points of view, suggested that the dissociation of strong electrolytes was much greater than appeared from the usual calculation on the basis of conductivity data. Milner (*Phil. Mag.*, 23, 551 (1912); 25, 743 (1913)) attempted to calculate quantitatively the effect of interionic forces, but owing to mathematical difficulties did not arrive at a strict solution of the problem.

In 1923 Debye and Hückel (*Physik. Z.*, 24, 185 (1923); 25, 97 (1924)) presented what appears to be a satisfactory solution of the problem. Briefly, their reasoning is as follows. Due to the Coulomb forces the "ionic atmosphere" surrounding any selected positive ion contains an excess of negative electricity. This causes an average electrical potential and an average electrical density different from zero to exist at any distance from the selected ion, the total potential and density being interrelated by the Boltzmann distribution principle and the Poisson equation. From this it is possible to calculate the increase in energy attending the removal of the n molecules constituting a gram molecule of any kind of ion, of valence z, from the "ionic atmosphere" (all other ions being simultaneously removed, their removal being attended by no other energy effects) by infinitely diluting the solution. Without following the mathematical derivation, it may simply be stated that they find that, for water as a solvent,

$$-\log_{10} f = 0.5z^2\sqrt{\mu}$$

where f represents the activity coefficient, z the valence of the ion, and μ the ionic strength defined by the equation $\mu = {}^1/_2\Sigma c_i z_i^2$. This limiting equation has been verified experimentally in the case of aqueous solutions.

Debye and Hückel extended the theory to the problem of conductivity also (*Physik. Z.*, 24, 305 (1923)). They showed that two factors cause a decrease in the mobility of the ions. The first is an "ion effect" due to the fact that the thermal equilibrium of the ions in the different configurations is disturbed by the migration of the ions, equilibrium being restored with finite velocity. The unsymmetrical arrangement of the ions creates an electric field which opposes the applied potential difference. The second effect arises from the fact that the ions tend to drag along solvent molecules according to the hydrodynamic laws for viscous media. About a given ion is found an excess of ions of opposite sign, so that the given ion has to move relative to a current of medium flowing in the opposite direction.

Taking into consideration the diminution in the mobility of an ion arising from these causes, Onsager (*Physik. Z.*, 27, 388 (1926); 28, 277 (1927)) derived the square root law of Kohlrausch

$$\Lambda = \Lambda_0 - a\sqrt{c}$$

and showed that a, the slope of the line, can be evaluated theoretically, the calculated and observed values of a being in good agreement.

In the field of weak electrolytes, the proper correction of the mobility for the effect of the "ionic atmosphere" has made possible the more accurate evaluation of the concentration of the ions. See, for example, Davies, *Phil. Mag.* (7), 4, 244 (1927), and Shedlovsky, Brown, and MacInnes, *Trans. Am. Electrochem. Soc.*, 66, 165 (1934).

To summarize: Owing to interionic forces the older method of determining the degree of dissociation of strong electrolytes is incorrect. All the evidence in the case of uni-univalent electrolytes seems to indicate that in aqueous solutions strong electrolytes of this type are practically completely dissociated. At the present time the corresponding dissociation constants are not known, because there is no physical property which is unquestionably due to undissociated molecules. In regard to weak electrolytes, correction of the mobility for the retardation caused by interionic forces leads to a more exact evaluation of the ionic concentrations.

EFFECT OF TEMPERATURE ON IONIZATION. The percentage to which a substance is ionized in solution may increase or decrease with the temperature. The sign and magnitude of the effect depend upon whether the ionization reaction is accompanied by an absorption or evolution of heat. Substances which dissociate with evolution of heat become less ionized with increasing temperature; substances which dissociate with absorption of heat become more ionized with rising temperature. Water, which is very

slightly ionized, belongs to the latter class. In general an increase of temperature from 0 to 100 deg cent produces a change in ionization of only a few per cent. Investigations by Noyes carried out at temperatures up to 360 deg cent have confirmed these predictions of theory. The effect of temperature on α may be computed through its effect on K by means of van't Hoff's thermodynamic relation

$$\frac{d \log K}{dt} = \frac{Q}{RT^2}$$

where K is the equilibrium constant of the ionization reaction, Q the heat of the reaction, R the gas constant, and T the absolute temperature.

NEGATIVE TEMPERATURE COEFFICIENTS OF ELECTRICAL CONDUCTIVITY. The fact that certain electrolytes, e.g., a phosphoric-acid solution, may have a negative temperature coefficient is readily explained in terms of the above relations. If the increase in the velocity of migration of the ions with rising temperature is more than offset by a diminution in the average number of free ions, resulting from a decrease in ionization, the conductivity of the solution will diminish. By combining solutions having positive and negative temperature coefficients in suitable proportions, electrolytes have been prepared which have nearly a zero temperature coefficient over quite a range of temperature. The following mixture, proposed by Manganini, has this property: 121 grams mannite, 41 grams boracic acid, 0.06 gram potassium chloride dissolved in sufficient water to make one liter. Its specific conductance at 18 deg cent is $\kappa = 0.00097$. Such a solution is well adapted for a liquid resistance just as manganine wire is adapted for resistance coils.

THE DEFINITION OF pH. Originally the term pH was introduced by Sörensen because of the form of the equation relating the free energy to the hydrogen-ion concentration, and $\log_{10} 1/c_{H^+}$ was called the hydrogen-ion exponent or pH. However, since the electrometric method was used in the determinations, and since the pH of the standard was based upon calculations of the hydrogen-ion concentration from conductivity data, the quantity measured was not that defined by the equation $pH = \log 1/c_{H^+}$. Accordingly a new definition, designated as p_aH, was later brought forward, p_aH being defined as $\log 1/a_{H^+}$ where a_{H^+} represents the hydrogen-ion activity. It is now realized that ionic free energies and activities cannot be evaluated without certain non-thermodynamic assumptions. The result is that pH's are really arbitrary values with the scale often varying from worker to worker, depending on: (1) the standard solution chosen, and the value assigned to it, and (2) the value of E_0 chosen for the cell used in referring to the standard. The cell employed is of the type

$$\text{Pt, H}_2 \mid \text{HCl, KCl} \mid \text{KCl} \mid \text{KCl, HgCl} \mid \text{Hg}$$

In order to determine E_0 it is necessary to evaluate the liquid junction potential.

The definitions of pH may be classified under three headings:

(1) $pH = -\log c_{H^+}$, the definition in terms of concentration.
(2) $pH = -\log 1.1a_{H^+}$, the "Sörensen" definition.
(3) $p_aH = -\log a_{H^+}$, the definition in terms of activity.

The second refers to pH's determined by use of Sörensen's value of the 0.1 N calomel electrode, or from the pH values of his standard buffer solutions, obtained therefrom. Most of the data in the literature are reported in terms of the second. There are certain advantages in the consistent use of the first definition. For a recent discussion see Kilpatrick and Kilpatrick, *J. Chem. Educ.*, 9, 1010 (1932).

THEORY OF LIQUID-LIQUID POTENTIALS. Nernst (*Z. physik. Chem.*, 4, 129 (1889)) was the first to show that in the case of electrolytes a difference of potential necessarily arises between two solutions in contact. The general theory has been worked out by Planck (*Ann. Physik*, 40, 561 (1890)) and by Henderson (*Z. physik. Chem.*, 59, 118 (1907); 63, 325 (1908)). Planck's formula applies to a junction in which the distribution of concentrations is maintained steady by artificial means, while that of Henderson may be described as a "continuous mixture layer."

Taylor (*J. Phys. Chem.*, 31, 1478 (1927)) and Guggenheim (*J. Am. Chem. Soc.*, 52, 1315 (1930)) have also considered a third type of junction which Guggenheim calls a "free diffusion" junction. The reader is referred to the papers of Taylor and Guggenheim for a discussion of the theory and the experimental realization of the conditions. Guggenheim finds that a reproducibility of 0.4 mv can be obtained with the Planck junction, and one of 0.2 mv with junctions of the "continuous mixture layer" and the "free diffusion" types. Guggenheim also points out that for a junction made at the end of a thin tube dipping into a wider one irregular fluctuations of several millivolts are obtained.

THE DEFINITION OF AN ACID. The usual definition that an acid is a substance containing hydrogen which in solution forms hydrogen ions, and a base a hydroxyl compound which forms hydroxyl ions in solution, was a natural result of the development of the

ideas of Arrhenius and Ostwald and the emphasis on aqueous solutions. A much more general and fruitful definition is that put forward by Brönsted (*Rec. trav. chim.*, 42, 718 (1923)) and Lowry (*Chem. & Ind.*, 42, 43 (1923)). Brönsted defines an acid by the formal equation

$$A \rightleftharpoons B + H^+$$

where H^+ represents the proton, A an acid of any charge whatsoever, and B the conjugate base of charge less by one than that of A. According to this definition the most common carrier of acid properties in aqueous solution, the hydrogen ion (H_3O^+), is only one of a number of acids.

$$H_3O^+ \rightleftharpoons H_2O + H^+$$
$$CH_3COOH \rightleftharpoons CH_3COO^- + H^+$$
$$NH_4^+ \rightleftharpoons NH_3 + H^+$$
$$H_2O \rightleftharpoons OH^- + H^+$$

Attention is also called to the fact that according to this definition the hydroxyl ion is only one of many bases.

The definition given applies to any solvent, emphasizes the acid, basic, amphoteric or inert nature of the solvent, and brings simplicity and order into the field. The definition has led to a number of important catalytic studies (see Brönsted, *Chem. Reviews*, 5, 284 (1928), and Kilpatrick and Kilpatrick, *ibid.*, 10, 213 (1932)).

15. ENDOSMOSE OR ELECTRIC OSMOSIS

If a current is passed along a film of water on a solid insulating surface, the water will be attracted to the negative electrode. Similarly an electric current flowing through a porous partition, or capillary opening, filled with conducting liquid, causes a flow of the liquid through the partition or opening. This phenomenon is known as endosmose or electric osmosis. For a review of the experimental and theoretical investigation of the phenomenon of endosmose see Schönfeldt, *Z. Elecktrochem.*, 39, 103 (1933).

The quantity of a given liquid which is carried through a given porous diaphragm in a definite time varies directly with the current strength and is independent of the area and thickness of the diaphragm. The quantity varies with the nature of the solution, being greater with liquids of high specific resistance and high specific capacity. The direction of flow is generally from positive to negative electrode, but under certain conditions the flow may be in the opposite direction.

APPLICATIONS OF ENDOSMOSE. Endosmose may be utilized to remove water from wet substances. Thus if a wooden box be equipped with perforated metallic plates at opposite ends and be filled with wet turf and current circulated through the turf from one end to the other, water will ooze out of the perforations of the cathode plate. Endosmose is utilized in tanning processes to accelerate the passage of tanning fluids through the hides. For a review of the industrial applications of endosmose see Schönfeldt, *Z. Elecktrochem.*, 38, 744 (1932).

ENDOSMOSE OF NEGATIVE FEEDERS. If electric conductors covered with a saturated braid or a number of such braids be made the cathode of a water bath and, say, 100 volts applied between anode and cathode, the braid will blister in a few minutes and the blisters will finally burst, grounding the conductor to the water. The same action goes on at lower voltages at a proportionately lower rate, but with equal certainty. No action is observable if the wire be made the anode instead of the cathode. Because of endosmose, insulation of low specific resistance should never be used on negative feeders. For the same reason it is not practicable to maintain a negative contact rail on electric railways, below earth potential, as the insulators soon become saturated with moisture and thereby become conductors (see Fortenbaugh, *Trans. A.I.E.E.*, 28, 1215, (1908)).

EFFECT OF ENDOSMOSE ON INSULATION MEASUREMENTS. When testing wires having insulation of low specific resistance, endosmose may further lower the resistance if the wire is negative to the water bath.

BATTERIES

PRIMARY BATTERIES

By C. F. Burgess

1. CLASSIFICATION

A *primary cell* is a device for producing electric current by electrochemical action. It is differentiated from a storage cell in that it is non-reversible and cannot be recharged efficiently.

A *primary battery* is a plurality of primary cells connected electrically. By common practice, however, the terms "battery" and "cell" are employed interchangeably.

ELECTRODES. In the primary cell, zinc is generally used as the negative electrode, or *anode*, which is attacked by the electrolyte. This zinc is metallically conductive, and to it is attached the negative terminal of the cell.

The positive electrode, or the *cathode*, is the conductive material to which the positive terminal is attached. The cathode must resist attack by the electrolyte. Some metals (platinum, gold) may be used, but conductive carbon rods have proved serviceable and are more economical.

ELECTROLYTE. The electrolyte is the solution, or liquid, which bridges the two electrodes and which conducts current while the cell is being discharged. A solution of sal ammoniac and zinc chloride in water is a typical electrolyte.

DEPOLARIZERS. The action of a primary cell depends upon the chemical action of the electrolyte upon the anode material, such as zinc. As a result of this chemical action, the anode goes into solution, releasing hydrogen at the cathode. This gas forms a film that lowers the electromotive force and raises the internal resistance of the cell so that no appreciable current can flow. This building-up of the products of reaction and consequent retarding of the desired processes is called polarization. To overcome this, a substance called a depolarizer is used. Certain metallic oxides are used as depolarizers, the most common being manganese dioxide, which is found abundantly in nature.

TYPES OF CELLS. It is by variations in construction that primary cells are given various characteristics and trade names. Thus, those cells which have a mobile liquid as electrolyte are called *wet cells*. In other cells the electrolyte is held or absorbed in a gelatinous or spongy material; these are non-spillable and are called *dry cells*. Of the great number of possible combinations of materials and methods of construction, the primary battery industry has settled upon the well-known " dry battery " as the major type.

WET CELLS. Less important, commercially, are the wet cells, exemplified by the Edison Lalande cell and the so-called air cell. In both of these, zinc serves as the anode, caustic soda solution as the electrolyte. In the Edison Lalande cell the cathode and depolarizer are a combination of copper and copper oxide. In the air cell the cathode is a porous carbon plate which is depolarized by the oxygen that it absorbs from the air.

DRY CELLS. The present day dry cell is an outgrowth of that combination of materials first suggested by Le Clanché. It uses zinc and carbon for electrodes, sal ammoniac and zinc chloride in solution as the electrolyte, manganese dioxide mixed with conductive carbon or graphite as the depolarizer. There is some polarization due to ammonia being formed, which zinc chloride is used to counteract.

The present primary battery industry has developed largely through empirical, cut-and-try methods—expediency, availability of materials, and cheap production being factors. In the early days of the electric era, the primary cell afforded the cheapest if not, in fact, the only practical source of electric energy. Today the cost of a kilowatt-hour from primary cells is 500 to 1000 times that of power from commercial circuits.

In spite of this wide discrepancy in unit power costs, the primary cell has an important place in the engineering and commercial world, because of certain important characteristics which it possesses: portability, availability at places remote from power circuits, minimum investment for a small generator, steadiness and uniformity of current, and flexibility in the combination of cells to produce batteries of any desired voltage.

The design of dry batteries has been influenced in large degree by the existing needs.

Thus there has been developed a battery known as a telephone battery to supply small energy drains over a long period of time, another type of battery called upon for ignition service, other types for flash-light, radio, and innumerable other uses.

The magnitude of the dry battery industry is indicated by the statistics for 1934, which show that about 500,000,000 cells were manufactured in the United States, representing a volume of business of about $30,000,000 at retail prices.

The uses for primary cells are:

(*a*) For portable lights, flashlights, electric lanterns.

(*b*) For electronic devices, including radio A, B, and C batteries.

(*c*) For telephone and hearing devices.

(*d*) For electromagnetic devices, including motors of both the rotating and vibrating types, fire alarms, signals, magnetic regulators, and the like.

(*e*) For spark or electrical discharges, such as in gas engine ignition, neon lights, ozonizers, and the like.

(*f*) For miscellaneous uses, which include electrolysis, electroplating, and medical uses.

2. DESIGN

Of all primary cells made, the dry battery type is by far the most important, having 95 per cent or more of the market. An excellent description of this type of cell is that published in Circular 79 of the Bureau of Standards, entitled, Electrical Characteristics and Testing of Dry Cells. The Bureau of Standards, in cooperation with the American Standards Association, has devoted much attention to an analysis of dry cells, and methods of use and tests. By them the various sizes have been designated by letter and dimensions, as shown in the following table. It is from cells of the dimensions given in this table that batteries using two or three cells in flashlights, to one hundred or more cells in radio batteries, are assembled.

Table 1. Constants of Tubular Cells

Types	Diameter		Length		Volume		Approximate Weight	
	Centimeters	Inches	Centimeters	Inches	Cubic Centimeters	Cubic Inches	Grams	Pounds

3. TESTING

The testing of dry cells for the determination of efficiency, life, and other characteristics is complicated by the variety of uses and requirements and by lack of manufacturing standards. From the Bureau of Standards' recommendations of tests designed for various classes of service and various types of batteries, Table 2 has been compiled, giving in a condensed form the adopted methods of testing.

As a means of comparing the merits of different makes of cells where the facilities for carrying out Bureau of Standards methods are not available, the so-called flash test will continue to be used extensively. This consists of measuring the momentary flow of current in amperes with the ammeter terminals connected directly to those of the cell. It has a definite usefulness in determining the uniformity of many cells of the same type and make, but unless properly interpreted, it is certain to be misleading. There are high-grade cells on the market that are specifically designed to give only a slight current on this test. In doing so the manufacturers are able to obtain increased storing qualities and greater life on the lighter drains more commonly employed in service.

Another quick test now in some favor among users is the continuous discharge of a cell through a flashlight bulb. This will show the value of the cell only for that use, and unless properly interpreted in connection with other tests will not indicate its value on intermittent or delayed service.

Table 2. Standard Dry Battery Tests

		Discharge Time	Resistance	Current Drain	End Point	Practical Use
		Flashlight Tests				
1.	4 ohm continuous	Continuously	4 ohms per cell	0.24 amp	0.75 volt per cell	Uniformity check
2.	Flashlight intermittent	5 min per day every day	12 ohms per 3 cells in series	0.28 amp	2.25 volts for 3 cells	Average city home use
3.	Heavy industrial	4 min every 15 min, 8 hr every day	12 ohms per 3 cells in series	0.29 amp	2.70 volts for 3 cells	Meter readers, watchmen, etc.
4.	Light industrial	4 min per hr, 8 hr every day	12 ohms per 3 cells in series	0 30 amp	2.70 volts for 3 cells	Farm use, campers, sports, etc.
5.	R.R. lantern intermittent	1 2 hr per hr; 8 hr per 6-day week	8 ohms per cell	0.15 amp	0.90 volt per cell	Railroad type lantern
6.	Heavy earphone intermittent	3 hr A.M. and 3 hr P.M. 6 days per week	15 ohms per cell	0.085 amp	1.0 volt per cell	Earphones
		Radio Tests				
7.	1250 ohms intermittent	4 hr per day, 6 days per week	83 1/3 ohms per cell	0.015 amp	17.0 volts for 15 cells	Average radio use
8.	1250 ohms continuous	Continuously	1250 ohms per 15 cells 83 1/3 ohms per cell	0.015 amp	17.0 volts for 15 cells	Police radio
9.	5000 ohms intermittent	4 hr per day, 6 days per week	5000 ohms per 15 cells 333 1/3 ohms per cell	0.0039 amp	17.0 volts for 15 cells	
10.	5000 ohms continuous	Continuously	5000 ohms per 15 cells 333 1/3 ohms per cell	0.0039 amp	17.0 volts for 15 cells	
		No. 6 Tests				
11.	10 ohms continuous	Continuously	10 ohms per cell	0.11 amp	0.90 volt per cell	Uniformity check
12.	Heavy intermittent	1 hr A.M. 1 hr P.M. 8 hr interval every day	10.5 ohms per 4 cells in series	0.44 amp	3.40 volts for 4 cells	Ignition service
13.	Light intermittent	4 min per hr 10 hr each day for 6 days; 4 min every other hr for 10 hr Sundays	20 ohms per 3 cells in series	0.194 amp	2.80 volts for 3 cells	Telephone service, doorbell, etc.
14.	Shelf	One yr at 70°	No drain			Depreciation due to storage

VARIATIONS IN PERFORMANCE. Since there is a variation in quality of cells depending upon their source, upon effects of shipment, and deterioration in storage, there may be wide variations in cells which reach the ultimate user. To determine the degree of this variation, an investigation has been conducted during the past year by an industrial laboratory. From dealers in New York, Chicago, Los Angeles, San Francisco, and Atlanta various popular brands of size D flashlight cells were purchased and sent to a central point for test by standard methods. The results given in Table 3 show the wide variation in quality of cells which are offered to the public.

Table 3. Variation in Performance of Commercial Cells

Test	Heavy Industrial	Light Industrial	Flashlight Intermittent
Time of Duration	½–3 days	4–24 days	100–190 days
Brand 1 (1)	300–360 min	800–900 min	900 min
Brand 2 (1)	220–250 min	480–500 min	730 min
Brand 3 and 4 (2)	160–210 min	300–440 min	500 min
Brand 5–18 (14)	130–200 min	200–300 min	650–740 min
Brand 19–23 (5)	100–180 min	140–280 min	600 min
Brand 24 (1)	160 min	390 min	
Brand 25–27 (3)	70–140 min	130–250 min	

Table 4 is a condensed compilation of many tests and is designed to show the performance which may be expected from the better-grade products available on the American market in 1934.

The results as shown in Table 4 were obtained under carefully controlled conditions as to age of cells (one week at start of test), temperature (70 deg fahr), and other particulars. Many factors affect the output of dry cells, some of the more important of which follow:

Age. At 70 deg fahr as much as 90 per cent of the original capacity is left in the size F cell at the end of a year. The amperage is not in this case a measure of capacity, and it usually falls off more rapidly than the actual service value. In general, smaller cells of the same grade will depreciate somewhat faster, but so many factors enter that it is impossible to set any definite figures for all sizes.

Heat. As the temperature increases, the rate of chemical action increases. Therefore, with increased temperature the following effects will be noticed:

(*a*) *Voltage* will rise in the order of 0.01 volt for each 13 deg fahr rise.

(*b*) The *amperage* will increase, and for a No. 6 cell this will be in the order of 1 amp for each 6 deg fahr.

(*c*) The capacity is nearly a straight-line function of the temperature of the battery during its discharge up to a certain maximum at above 100 deg fahr. The following table shows the capacities on continuous discharge at different temperatures, in percentage of that obtained at 70 deg fahr.

Temperature	−15° F	70° F	100° F	150° F
Size A on 333 ohms	27%	100%	127%	121%
Size D on 333 ohms	24%	100%	146%	114%
Size F on 83 ohms	13%	100%	140%	

The shielding of batteries against excessive temperatures is important. It must be borne in mind that when a cell is brought back to a high temperature from a lower one the characteristics for the higher are assumed, but if it has been overheated, then lowering the temperature will decrease the capacity still further.

(*d*) *Storage.* In that the rate of chemical action is increased, the local action within the cell will increase with rising temperature so that cells depreciate considerably faster. This is mainly due to increased local action, but in some cases also to the increased rate of loss of moisture. Dry cells should be stored in a cool place. Temperatures down to minus 10 deg fahr have not been found detrimental.

Type of Discharge. In a constant current discharge the same amperage is obviously drawn from the cell during all stages of its life. With constant resistances more current is drawn at the start and less at the end owing to the difference in voltage. Thus, as would be expected, on a constant resistance discharge the rate of change in voltage is greater at the start than at the finish. Even though the shape of the curve is changed, however, if the drain on constant resistance is considered as the average ampere value to any given end voltage, then the ampere-hours delivered to that voltage will be practically the same as though the cell had been discharged constantly at that amperage. The action of lamps is somewhat between these two types of discharge.

Table 4. Capacities of Various Cells

Cell	AA	A	B	C	CD	D	F	G	6
	Light Drain—Flashlight Type								Telephone

Intermittent Drains. These can be related to continuous drains, but it must be remembered that each type of cell has a specific rate of discharge at which it delivers its maximum amount of power. If a cell is being run on a drain heavier than this optimum, then a lighter drain or an intermittent drain of fewer hours per day will increase the capacity of the cell. If, on the other hand, the cell is being discharged at a slower rate than its optimum, then decreasing the rate of drain or time of discharge per day will decrease the life of the cell. In general a factor can be determined for each type of cell. This is sometimes called "severity of service." It is the product of the percentage of total time during which the cell is discharged and the current drain. Except for very heavy drains, a cell being discharged at several rates but at the same severity of service will deliver the same energy.

Closed-circuit Voltage. On the heavier type of service considerably more power is obtained from the cell to lower voltage end points than to higher ones, but on lighter drains the current is delivered at relatively higher voltages so that when the end of the life of the cell is reached the materials are generally used up and the cell passes through the various lower voltages in a very brief period of time. In the former case, it can be figured roughly that the same period of time will elapse between the initial closed-circuit voltage and 1.25, 1.25 and 1.00, 1.00 and 0.75, and between 0.75 and 0.50. This rough slope of the discharge curve is fairly constant even for a wide range of temperatures.

4. INSTALLATION

Depending on the rate of discharge * desired and the point of maximum efficiency of the cell to be used, cells may be connected in parallel. Thus if the drain is too great for efficient use of one cell, the positive terminals of several cells may be connected together and the negative terminals connected, thus having the effect of one considerably larger cell. This does not merely increase the power obtained by the number of cells chosen, but by reason of the more efficient service the increase will be much greater than the mere additive values. If the drain is too light for one cell, then adding more in parallel will reduce the power delivered by each. When higher voltages are needed the cells are connected in series, plus to minus. Table 5 shows the life in ampere-hours obtained from various cells of good quality on continuous and intermittent drains.

Table 5. Variation in Ampere-hour Capacity

Cell Size—F	Capacity in Ampere-hours to 0.9 Volt						
	Milliampere drain	..	3	5	25	50	100
	Hours per day	3	9.1	9.0	10.1	10.1	8.1
	Hours per day	6	11.5	10.7	10.4	9.2	7.4
	Hours per day	24	12.6	11.2	6.9	5.5	4.2
Cell Size—B	Capacity in Ampere-hours to 0.9 volt						
	Millampere drain	..	1	3	10	25	50
	Hours per day	3	1.5	1.6	1.8	1.6	1.0
	Hours per day	6	2.0	1.9	1.7	1.4	0.92
	Hours per day	24	2.2	1.6	1.1	0.8	0.6

5. OPERATION

One important factor in the use of dry cells is that any cell if run down continuously far below its normal service end point will eventually leak. This leakage will occur either through the seal or through the zinc itself if the latter is thin enough to perforate in service. The solution discharged from a leaking dry cell is about 60 per cent zinc chloride in water. The effect of this on the materials used around dry cells will generally be serious. Even if a cell is open-circuited after it has been seriously run down, the tendency to leak will still remain. Thus if cells have been accidentally short-circuited or used continuously until they are dead, the only safe action is to remove them so that they can do no damage. In general, it will be found that cells delivering a high short-circuit amperage and greater service on heavy continuous discharge are more apt to leak. With the present state of the art there is very little danger from this source if cells are purchased from a reputable manufacturer and are properly treated.

* For Specifications see Circular of Bureau of Standards 79.

LEAD-ACID STORAGE BATTERIES

By J. Lester Woodbridge

6. GENERAL AND DESCRIPTIVE

The action of a storage battery when discharging is similar to that of a primary cell except that the material of the electrodes which undergo the chemical reactions is not dissolved but remains in much the same mechanical condition as before discharge. When this requirement is fulfilled the material of the electrodes can be restored to its original condition by " recharging " or passing a current through the cell in the reverse direction to that of the discharge current. When this is done the electrical energy of the charging current is transformed into chemical energy and stored as such in the electrodes.

As there is no loss of material during the discharge of such a battery to expose fresh material to chemical action, it is necessary that the active material of the electrodes either be disposed in a very thin layer over a large surface or be porous to permit the use of the interior part of thick material.

LEAD-ACID BATTERY. A lead-acid cell consists essentially of positive plates of lead peroxide and negative plates of pure lead immersed in an electrolyte of dilute sulfuric acid.

(In accordance with common engineering parlance the terms positive and negative plates are employed in this article to denote respectively the plates which are connected to the positive and negative terminals of the external circuit on both charge and discharge. The term battery is employed to denote a *group* of two or more cells which constitutes an operating unit.)

CHEMICAL REACTIONS. The active elements of the lead-lead acid type of battery consist of lead peroxide (PbO_2) on the positive plate, sponge lead (Pb) on the negative plate, and dilute sulfuric acid (H_2SO_4) for the electrolyte.

Whatever the secondary reactions may be, it is agreed that the final result on discharge is the formation of lead sulfate ($PbSO_4$) on both the positive and negative plates, the SO_4 radical of the sulfuric acid combining with the lead of both plates to form this compound, resulting in the formation of some water (H_2O), with a consequent decrease in the specific gravity of the electrolyte. On charge the electric current splits up the lead sulfate ($PbSO_4$), returning the SO_4 radical to the electrolyte, oxidizes the positive plate to its original condition of lead peroxide (PbO_2), and reduces the negative plate to its original condition of sponge lead (Pb). This action may be represented as follows:

$$\underset{+\text{Plate}}{PbO_2} + 2H_2SO_4 + \underset{-\text{Plate}}{Pb} \rightleftarrows \underset{+\text{Plate}}{PbSO_4} + 2H_2O + \underset{-\text{Plate}}{PbSO_4}$$

This equation read from left to right is the equation of discharge; if read from right to left, it is the equation of charge. In practice, on charge, towards the end of charge some of the water (H_2O) is split up by the current into its component parts, hydrogen (H) and oxygen (O), the hydrogen being liberated at the negative plate and the oxygen at the positive plate. This occurs whenever the density of charging current is greater than can be utilized in decomposing the lead sulfate remaining in the plates.

Types of Lead-Acid Cells

Two general types of lead-acid batteries are in use, the Planté and the pasted plate, each type being subject to some modifications. The distinction between these types is based on the plate structure.

PLANTÉ TYPE. The Planté plate is essentially a pure lead plate having a highly developed surface presenting a large superficial area which is oxidized electrochemically until the entire surface is covered with a thin, porous layer of lead peroxide (PbO_2). This constitutes a positive plate. It may, however, be converted into a negative plate by reversal of the current which reduces the lead peroxide to pure lead in a porous form. Planté negative plates are little used at this time.

Planté Plates. Of the various types of Planté plates, among those most commonly in use may be mentioned the central-web type and the cast-lead having no central web. The main idea in both these methods of manufacture is to produce a large surface on which to form the active material.

Central-web Type. In the central-web type there is a solid sheet or "web" of pure lead on which the ribs are formed. This web prevents the circulation of the electrolyte through the plate. The ribs are formed from the original lead plate, either by rolling, spinning or cutting. In the rolling and spinning processes the plate is formed from a lead blank by means of a number of steel disks placed side by side and separated by small spacers on a shaft. The lead blank is passed between two sets of disks by forward and backward movements. The disks gradually work deeper into the plate and squeeze up lead into the spaces between the adjacent steel disks. In the cut type of plate the ribs are formed from the lead sheet by a tool, which at each stroke turns up one complete rib. The cutting edge works at an angle so that the finished ribs stand out from the surface. The ribs may incline upward from the central web and thus form pockets to hold the active material and prevent its falling away.

The disadvantage of the *web* type is the web itself. There is invariably a tendency towards unequal work on the two sides of the positive plate, this tendency being caused by difference in the plate spacing, unequal capacity of the negative plate on either side, inequality in the shape of the ribs, etc. Where the active material and the active surface of a plate are disposed in planes perpendicular to the face of the plate and extend *through* the plate, excessive action on one side simply works the plate a little further through from that side, the effect on the active material, however, being uniform throughout. With a plate provided with a central web, preventing such action, any inequality of work will charge or discharge one side more than the other, producing a tendency to buckle.

Cast-lead Type. The type of plate which has no central web is made by casting pure soft lead in a mold, casting having the advantage of allowing for distributing metal in the plate without limitations in manufacturing process. The plate as it comes from the mold consists of a great number of short vertical ribs running entirely through the plate and bound together by transverse ribs to give strength to the plate. In this manner a large surface can be obtained and in a plate having no central web the electrolyte can circulate through the plate, and the active material will be uniformly worked throughout even though the amount of work on the two sides of the plate be unequal. The best-known form of this plate is the " Tudor " positive.

Modified Planté or Manchester Positive Plate. The so-called Manchester positive plate is made by rolling corrugated strips of pure lead ribbon into rosettes or " buttons " which are forced into circular openings in a rigid grid of cast lead-antimony alloy. This grid is strong, stiff, and subject to very little electrolytic corrosion; it therefore provides a plate structure which is immune from the growth and buckling which frequently occurs with Planté plates composed entirely of pure lead. The pure lead buttons constitute the active part of the plate and function in every way similarly to the original Planté positive plate.

"Forming" of Planté Plates. In all Planté positives, after the ribs or corrugations have been formed on the lead blank or the pellets have been placed in the hard grid, the plates are assembled in a sulfuric acid bath containing some corrosive chemical, called a " forming agent," together with dummy lead plates. The forming agents used by various manufacturers are usually kept as trade secrets; the nature and method of using such agents determine largely the quality of the battery. To form the positive plates the dummies are connected as the cathodes, and a current is passed through the couple thus formed. The electrolytic action of this current causes lead peroxide (PbO_2) to be formed from the lead of the ribs. . The strength and duration of the current produce the desired thickness of lead peroxide on the ribs or pellets.

In recent years the Planté plate has largely disappeared from use in this country while the Manchester positive plate has continued in extensive use. In Germany the Planté positive plate has been used to the practical exclusion of the Manchester type. At the present time (1936) the offering of Planté positive plates has been more actively resumed by at least two manufacturers. It is therefore probable that the use of this type of plate in this country will increase.

The Planté and modified Planté types are used chiefly where space, weight, and first

cost are of secondary importance and where a battery more durable than the pasted plate type is desired.

PASTED PLATE TYPE. The pasted plate is made by applying to a rigid grid of cast lead-antimony alloy the active material in the form of a paste composed largely of lead oxides, usually litharge (PbO) or red lead (Pb_3O_4) or both, and a solution containing sulfuric acid or a sulfate which acts as a binder. The grid usually has the form of a double gridiron composed of a series of vertical ribs which extend through the plate, giving it strength and providing conductivity to carry the current to plate lugs. These vertical ribs are tied together by short cross-bars which are flush with the surface but extend only partly through the plate and are staggered on opposite sides. These short bars are usually horizontal, but one manufacturer places them diagonally making the so-called diamond grid. In either case the active material when applied to the grid is disposed in the form of corrugated strips or ribbons extending from the top to the bottom of the plate between the vertical ribs and held in place by the cross-bars.

As the active material has a depth equal to the thickness of the plate, composition of the paste must be such as to result in the necessary porosity while still maintaining sufficient strength and cohesion of the material to assure the desired life of the plates in service. The composition of paste used is varied for different services, and the variations are closely guarded trade secrets.

Plates of this type are very extensively used as both positive and negative, but in the composition of the paste red lead usually predominates for positive plates and litharge for negative plates.

After the grid is filled with the paste, the plate is dried to allow the paste to harden, then it is "formed" electrochemically. Positive plates are formed by immersing them in a forming bath and passing current through them connected as anodes which further oxidizes the lead oxides in the dried paste forming lead peroxide (PbO_2). Negative plates are formed by passing the current in the opposite direction which reduces the lead oxide to sponge lead. After the forming charge the plates are washed and dried and are ready for assembly.

Quite recently processes have been developed which permit the dried pasted plates to be assembled into cells and the plates to be formed while in the assembled cells. This process has been used only for cells which are manufactured in large quantities.

Modified Pasted Plate or Exide Ironclad. In the so-called Exide-Ironclad positive plate, the active material is prepared from lead oxides of composition similar to that used for pasted positive plates. This plate is therefore generally classed as a pasted plate although the plate structure differs entirely from the usual flat plates of that type. The frame of this plate consists of a series of parallel vertical core rods joined at each end to horizontal top and bottom bars all of lead-antimony alloy. The active material completely surrounds each core rod and is held in place by finely slotted rubber tubes. The core rod is thus in the center of a cylindrical pencil of active material where it is well placed to conduct the current to the top bars and the cell terminals. The effective surface of the active material exposed to the electrolyte is greater than in a flat plate type of equal superficial dimensions. The slotted rubber tube replaces the perforated rubber separators used with flat plates and acts more effectively to retain the active material in place as it softens with use and thus makes a plate having a longer useful life. Its first cost is greater than that of the usual flat plate type, but it is claimed by its manufacturer to give from 2 to 3 times the life in severe service.

This type of plate has come into very extensive use especially in motive power work, railway train lighting, and marine service.

ELECTROLYTE. The electrolyte used with the lead type of battery is always a dilute solution of sulfuric acid. The specific gravity of the electrolyte, when the battery is fully charged, varies from about 1.210 for stationary batteries to 1.300 for automobile ignition batteries. These values have been adopted as standard by all the leading manufacturers.

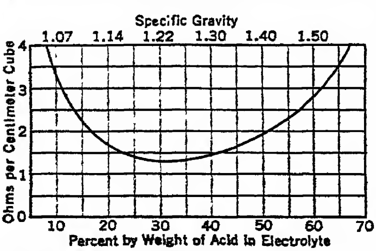

FIG. 1. Variation of Resistance with Specific Gravity

The proper specific gravity to use varies with the conditions. Fig. 1, showing the variation of the resistance of 1 cc of electrolyte with specific gravity shows that the resistance of dilute sulfuric acid is least at a specific gravity of from 1.224 to 1.240, this resistance increasing if the specific gravity be either increased or decreased. Numerous other conditions influence the selection of the proper specific gravity.

The curves in Fig. 2 show the specific gravity of various mixtures, both by weight and by volume, of one part of 1.840 specific gravity acid with from $^1/_{10}$ to 7 parts of water. There is also a curve showing the percentage, by weight, of 1.840 specific gravity acid in mixtures of various specific gravities. These curves are approximately correct at 60 deg fahr. Unless a compensating hydrometer is used in determining the specific gravity, allowance must be made for temperature variation, on the basis of an increase of one point (i.e., one one-thousandth) in gravity for each 3 deg fahr *decrease* in temperature, and vice versa; for instance, electrolyte that has a specific gravity of 1.210 at 70 deg fahr will have a specific gravity of 1.213 at 61 deg fahr, and 1.207 at 79 deg fahr.

Impurities in Electrolyte. The electrolyte should be of known purity, harmful ingredients such as iron, chlorine and nitrogen oxides being strictly limited. The various battery manufacturers issue exact specifications to the acid manufacturers, specifying the maximum amount of different impurities which the acid may contain. Electrolyte that is not approved by the company furnishing the battery should never be used.

Preparation of Electrolyte. In preparing the electrolyte, sulfuric acid, approved by the battery manufacturer, should be diluted with sufficient pure distilled water to bring the mixture to the required specific gravity. The acid should be poured into the water; *never pour the water into the acid.* If the water is poured into the acid, the heat formed by the mixture is sufficient to cause sputtering and damage may ensue.

The sulfuric acid manufacturing companies furnish electrolyte for battery work in such large quantities that they carry a stock of various standard mixtures. It will usually be found cheaper and more convenient to purchase the electrolyte ready-mixed than to purchase the concentrated sulfuric acid and prepare the mixture on the ground. The latter course, however, is sometimes adopted where the amount of acid used is considerable and where the item of freight saving is appreciable.

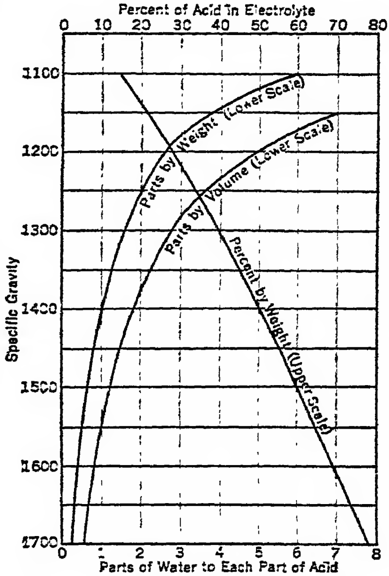

FIG. 2. Variation of Specific Gravity with Concentration

CONTAINERS. The containers for holding the battery plates and electrolyte may be of hard rubber or asphaltic compound, glass, or lead-lined wooden tanks depending on the size of the cells and on the nature of the service.

Rubber Containers. Hard rubber or composition containers are used when the cells must be portable or subject to mechanical shocks while in service. Typical examples of such cells are those used for automobile starting and lighting, electric street and industrial trucks, railway train lighting, submarine boat propulsion, etc.

In these batteries the plates are usually supported on ribs in the bottom of the jars, the ribs being of sufficient height to allow ample space for the accumulation of sediment, deposited owing to the gradual loss of material from the plates, without danger of its short-circuiting the plates. The chemical composition of the rubber compound is subject to the specifications of the battery manufacturer in order to prevent contamination of the electrolyte.

Glass Jars. Glass jar containers are used in preference to rubber containers whenever the service and size of the cells permit, on account of the greater ease of inspection and maintenance. The present tendency is toward the almost exclusive use of the cells assembled sealed and charged at the manufacturer's plant and shipped filled with electrolyte and ready for service as soon as installed and connected. This assembly is available in cells up to approximately 1000 amp-hr capacity at the 8-hr rate for pasted plate types and up to about 550 amp-hr for the formed plate types. Thoroughly annealed molded glass containers for from 1 to 3 cells are used for the smaller sizes and to a limited extent by some manufacturers for the larger sizes of single cells, but the internal strains which remain even after the most careful annealing and the higher cost of the molded jars have resulted in the much more extensive use of machine-blown jars for the larger cells. These jars are also thoroughly annealed.

In blown jar assemblies the plates are usually supported from the cover of the cell but in some cases separate supporting ribs are placed on the bottom of the jars. In molded jar assemblies ribs may be molded on the jar bottoms to support the plates.

Lead-lined Tanks. In the larger sizes of batteries lead-lined tanks are standard. Tanks are generally made from specially selected yellow pine, dovetailed together without the use of nails or other metallic fastenings. The upper edges should be slightly beveled inward so that the moisture will drain into the tank. The bottoms under the linings should be drained and ventilated; these bottoms are usually constructed of slats across the tanks, separated by a small spacing to provide drainage. To further facilitate drainage under the lining, the upper surface of these slats should be grooved crosswise. Before the tanks are lined they should be coated inside and outside with two coats of acid-resisting paint, and a third coat should be added outside during installation. The tanks should be lined with lead of 3 to 4 lb per sq ft, depending on their size. The lining should extend over the upper edge of the tank and a short distance down, but free from, the sides. Especial attention should be paid to the seaming of the linings. All seams should be burned with the hydrogen flame with pure lead, without the use of any flux. The lower corners of the lining should be reinforced by puddling with lead. The upper corner should be reinforced by burning on an additional thickness of sheet lead. Each tank should be so built that it is self-supporting without the use of any braces or reinforcements. If this is done, any tank in the battery can be removed and replaced without affecting the remaining tanks in any way. A poorly constructed wood tank is bound to cause trouble. Special attention should be paid to this detail in preparing specifications.

In cells of this type it is of course necessary to insulate the plates from the lead lining. The plates are therefore supported on vertical sheets of glass resting on the bottoms of the tanks. The tank linings under the glass sheets are reinforced. The glass sheets are ground smooth on the top and bottom edges, and the bottom corners are beveled at 45 deg to avoid injury to the lead lining during installation.

Cell Covers. Batteries in lead-lined tanks and in the old forms of open glass jar assemblies are usually provided with covers of double thick window glass which rest on the top of the cells. These covers serve the purpose of intercepting much of the fine spray thrown off from the surface of the electrolyte during " gassing " while charging and drain it back into the cell. They also serve to keep dirt out of the cells, this being quite essential when the air is likely to contain particles of metal or other matter injurious to the battery.

Both these purposes are served very much more completely with the sealed type of cell in either glass or rubber jars. In the blown-glass jar assembly where the plates are supported from the cover, the cover must be of sufficient strength to carry this weight even during shipment. It must also be impervious to the action of the electrolyte, and not affected by any temperatures which are likely to be encountered either during shipment or in subsequent service. Molded glass and hard rubber or similar compounds are materials most frequently used.

For sealed glass jar cells the covers are provided with a groove on the under side which fits over the edge of the jar, this groove being partially filled with a sticky plastic sealing compound which under the weight of the plates forms a tight seal between the cover and the jar. The joints between the cover and the cell terminal posts must be sealed to prevent creepage of electrolyte over the top of the cell. This is effected by sealing compound or by some form of gasket clamped between the cover and the terminal post by means of a threaded seal nut.

For rubber jar cells the covers are so shaped as to provide a V-shaped groove between the cover and the jar sides, which is filled with sealing compound. The seal between the terminal posts and the cover may be as described above for glass jar cells but in some types of automotive batteries this is accomplished by means of a lead thimble molded into the cover through which the terminal post passes. This thimble is then " burned " to the terminal post to complete the seal.

Separators and Separation. Since the positive and negative plates of the cells are assembled alternately, it is necessary that " separators " be provided to prevent their coming in contact with each other and so short-circuiting the cell. These separators must maintain their mechanical strength throughout the life of the battery and must be porous to allow diffusion of the electrolyte through them and the passage of the current through the electrolyte in their pores. Grooved wooden diaphragms, perforated hard rubber sheets, or a combination of both are ordinarily used. The woods most commonly used for separators include cedar, cypress, redwood, and Douglas fir. They may be cut as veneers, quarter sawed, or sliced. They are usually planed to the exact thickness required and to provide grooves for the circulation of the electrolyte and free passage of loosened material to the sediment space at the bottom of cell. Wood separators are treated chemically to

remove ingredients which when in contact with the sulfuric acid in the electrolyte will form acetic acid which is injurious to the plates.

The threaded rubber separator as used by the Willard Storage Battery Co. is composed of a semi-hard rubber sheet in which are imbedded cotton threads running transverse to the thickness of the separator to provide the required porosity.

Glass wool separators are used by the D. P. Battery Co. in England and the Gould Storage Battery Co. in this country in the so-called Kathanode battery. This form of separator is composed of fine glass fibers laid at different angles and cemented on the surface with a soluble cement to permit handling prior to assembly in the cell. It is placed against the positive plate where owing to its compressibility it comes into intimate contact with the plate and prevents or retards the softened material on the surface of the plate from falling to the bottom of the cell. It is used in conjunction with wood or with wood and perforated rubber separators.

The Electric Storage Battery Co. announced in 1934 a new type of separator under the trade name of Mipor. This separator is manufactured from rubber latex to which are added the sulfur required for subsequent vulcanization and certain other ingredients which cause the rubber content of the latex to partially coagulate into a jelly-like form which constitutes a three-dimensional network in which the water content of the latex is enmeshed.

When this jelly is sufficiently set it is vulcanized in the presence of water or saturated steam to prevent the collapse of the rubber mesh into the space occupied by the enmeshed water.

On completion of vulcanization and after drying, the material has all the characteristics of hard rubber except that it is highly porous. The pores are of microscopic dimensions (in the order of 0.00004 cm or 0.000016 in.) which prevents the penetration of even the smallest particles of active material, but the pores are so numerous as to permit ample diffusion of the electrolyte and ready passage of the electric current. The body of the separator being of hard rubber is unaffected by the electrolyte or by high temperature. This separator has a conductivity somewhat better than that of the corresponding wood separator.

7. CELL CHARACTERISTICS

A lead-acid cell has an open circuit voltage of approximately 2 volts regardless of the size of the cell. This voltage is, however, somewhat dependent on the specific gravity of electrolyte used, being approximately 2.06 volts per cell with 1.210 specific gravity and

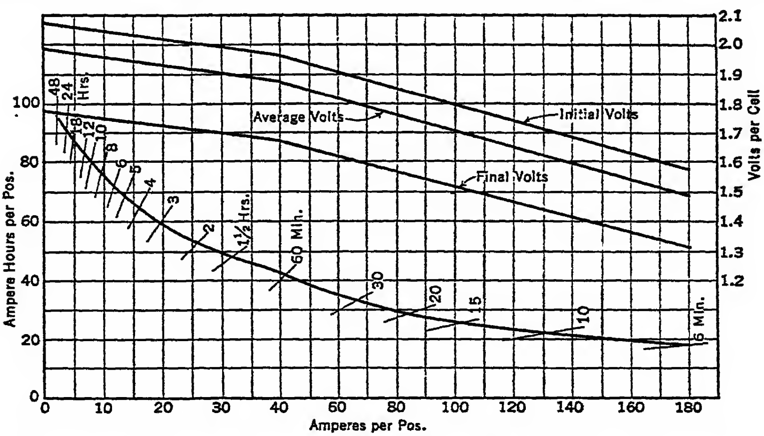

Fig. 3. Rated Disharge Characteristics of Lead-acid Cells, 1.210 Sp. gr., 77 deg fahr

2.10 with 1.280 specific gravity. A sufficient number of cells are connected in series to get the desired voltage of a battery.

The capacity of a cell or battery is usually expressed in amperes and time, as 20 amp for 8 hr, or as 160 amp-hr at the 8-hr rate, which is the same thing. The capacity desired determines the size of cells used in a battery. To define the capacity of a cell or battery completely it is also necessary to specify the minimum voltage permissible at the end of

the discharge period as 20 amp for 8 hr to a final voltage of 1.75 volts per cell. Manufacturers are usually prepared to furnish data giving the electrical characteristics of their different types of cells. Fig. 3 shows the usual form of such data. They are given in terms of amperes and ampere-hours per positive plate, and the voltages are for a single cell. These data are applicable to all sizes of cells using that size and type of plate.

In this country batteries are generally designated by a series of numbers and letters, as 60–EMGO–9, meaning 60 cells each having 9 plates, the letters being a code designating the size and type of plate and details of the cell assembly. As there is usually one more negative than positive plate in a cell and as the capacity is limited by that of the positive plate, a graph of the type given in Fig. 3 may be used for determining the capacity in ampere-hours and the initial, average, and final voltage of any size of battery of the designated type at any rate of discharge.

The capacity of the battery as given in ampere-hours is to be taken as the capacity which the manufacturer undertakes to deliver after the battery has been installed and is ready for an acceptance test. Practically all types of lead-acid batteries will increase their capacity during the first few months of service and will maintain this increased capacity during the greater part of their useful life.

The final voltage values as given define the minimum voltage at the end of a continuous discharge at any particular rate. It is true that some additional capacity can be obtained to lower final voltages, but the increase will not be great, as the voltage will fall quite rapidly if the discharge is continued. Although the final voltage values may be considered somewhat arbitrary, a definite value is necessary for test purposes, and those assigned meet all practical requirements.

The average voltages given are those which can be computed from frequent periodic readings during a continuous discharge at the specified current to the final voltage given. These values are used principally for determining the size of battery required to carry loads expressed in kilowatts and kilowatt-hours.

The initial voltages given are again somewhat arbitrary, as the instantaneous voltage that can be observed on closing a circuit may change quite rapidly during the first few seconds depending on what work the battery may have been doing for some little time prior to closing the circuit. The duration of this rapid change also depends on the rate of discharge. These transient voltages are seldom of engineering importance, and the values as given are substantially correct as representing the stabilized value which will exist after a short interval.

CAPACITY CHARACTERISTICS. The relation between capacity and rates *of continuous discharge* are given in graphs of the character shown in Fig. 3. The reduced capacity at higher rates of continuous discharge is due to depletion of acid in the electrolyte in the pores of the plates. During discharge the acid in the electrolyte combines with the active material of the plates and water is formed, thus reducing the strength of the electrolyte inside the plate. This effect is counteracted to a varying extent by diffusion between this weakened electrolyte in the plate and the stronger electrolyte outside the plate. At higher rates of discharge the electrolyte inside the plate is weakened faster than it can be replaced by diffusion. It is this depletion of acid in the pores of the plates that limits the capacity at high discharge rates, not any limitation in the plates themselves. If the discharge is interrupted, diffusion will of course continue, and this brings about the well-known recuperation of a battery during idle periods. The available capacity of a battery is therefore really a function of the total elapsed time of discharge rather than of the rate of discharge. The two are the same for a continuous discharge, but for intermittent discharge the capacity varies with the total elapsed time. Inasmuch as it is a lack of available acid that reduces the capacity at high rates of continuous discharge it is evident that the battery cannot be damaged by excessive discharge at such rates.

VOLTAGE CHARACTERISTICS. The initial, average, and final voltage lines as shown in Fig. 3 are straight lines showing a drop in voltage which is proportional to the current. This suggests that the drop is an IR drop and that the internal resistance of a cell can be calculated from these data. Although such a value can be used in some classes of calculations it is by no means of universal application. The true internal resistance of a cell is of little engineering importance, and in fact when measured by different methods in a laboratory widely varying results may be obtained. It is generally accepted that during a continuous discharge the internal resistance increases slowly during the first two-thirds of a discharge and increases at an increasing rate to a value at the end of a complete discharge approximately twice as great as at the start.

Fig. 4 shows the variation of voltage with time during continuous discharge at rates from the 24- to the 3-hr rate. The drop of voltage with time is due partly to the increase in internal resistance and partly to the reduction of electrolyte density in the pores of the plates (the latter effect is frequently referred to loosely as polarization).

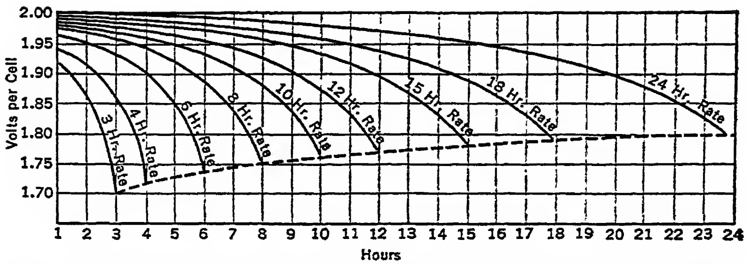

Fig. 4. Approximate Volt-time Curves for Batteries in 1200–1220 Sp. Gr. at 70°–80° F.

EFFECT OF TEMPERATURE ON CHARACTERISTICS. In data showing the characteristics of their different types of cells, manufacturers usually follow A.I.E.E. standards and base them on a temperature of electrolyte at the start of a test of 25 deg cent (77 deg fahr). Temperature affects both the internal resistance and the rate of diffusion of the electrolyte in such a way that both the capacity and voltage are lower at lower temperatures and higher at higher temperatures. It is impossible to make a general statement of the quantitative effects of temperature changes as they vary greatly with details of plate structure and assembly, and with the discharge rates. Fig. 5 gives data on one type of battery at two rates. The internal resistance of a battery, as determined from the momentary change in voltage with change in current, is approximately doubled by a drop in temperature from 25 deg cent (77 deg fahr) to 6 deg cent (20 deg fahr), this variation being in approximately a straight line between these limits.

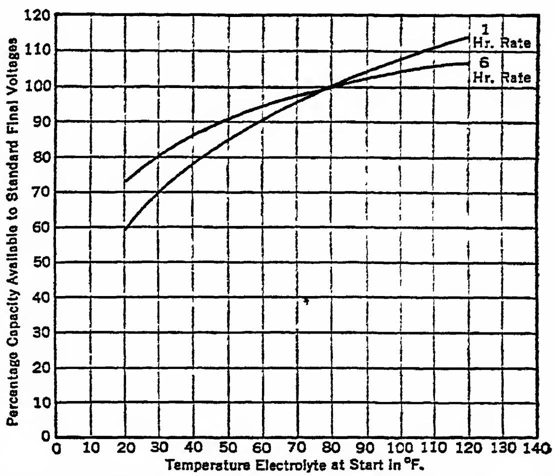

Fig. 5. Variation of Capacity with Temperature. Ambient Temperatures Constant at Values Shown. Capacities shown are to standard final voltages. Additional useful capacity will be obtained at the lower temperatures if discharges are continued to the knee in voltage curve

CHARGING CHARACTERISTICS. The electrical characteristics of a battery on charge are usually of little interest except in choosing charging equipment that will be both economical and convenient. A wide latitude as to charging rates is permissible with lead-acid batteries, the essentials being that the rates shall be such as to avoid excessive temperatures (about 45 deg cent — 113 deg fahr) and excessive gassing. These requirements demand that relatively low charging rates be used during the latter part of the charge. Manufacturers usually assign a rate which should not be exceeded at that time and which is generally called the "finishing rate." A general rule for determining the maximum permissible charging rate has been given as: The charging rate in amperes must not exceed the ampere-hours out of the battery unless the rate be the finishing rate or lower. This rule permits charging of an empty battery at rates too high to be convenient or economical but shows the wide latitude permissible between such charging and a constant current charge at the finishing rate which may require 16 hours or longer. Automatic charging may be done by the so-called modified constant voltage method which consists of a constant voltage charging source equal to approximately 2.6 volts per cell of battery and a fixed resistor between this source and the battery. Fig. 6 shows complete records of a battery charged in this manner. This method of charging is strongly recommended when batteries are to be charged frequently and in comparatively short time.

Constant current charging at the finishing rate or less is satisfactory if time is available.

When batteries are to be charged infrequently manual control of the charging current is frequently employed using a constant current at the finishing rate or a current about 2.5 times the finishing rate during the early part of the charge, then reducing the rate to the finishing rate. Fig. 7 shows the variation of voltage during such a two-rate charge.

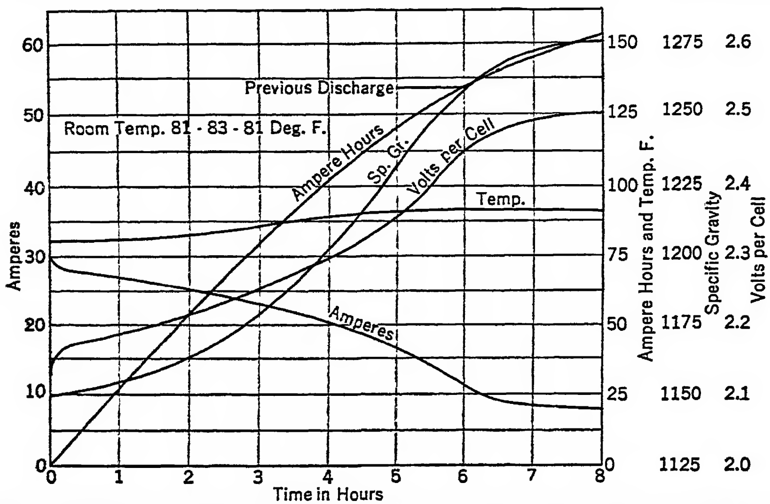

Fig. 6. Modified Constant Voltage Charge. 4 cells. 136 amp hr capacity in 6 hrs. Charged from 10.52 volt bus, 2.63 volts per cell, through fixed resistance of .0665 ohm. Ohm per cell = 0.0166

Trickle Charging is a term applied to maintaining a very low charge rate which is of the proper value to compensate for the internal losses which occur in an idle battery. It is employed to keep a battery in a fully charged condition over long intervals (see also Standby Batteries). The proper value of the trickle charge current depends on size and number of plates per cell, the specific gravity of the electrolyte, the temperature, and the age and condition of the battery. It is usually in the order of 0.1 per cent of the 8-hr rate for 1.210 specific gravity and temperature near 25 deg cent (77 deg fahr), but a more accurate value should be obtained from the manufacturer.

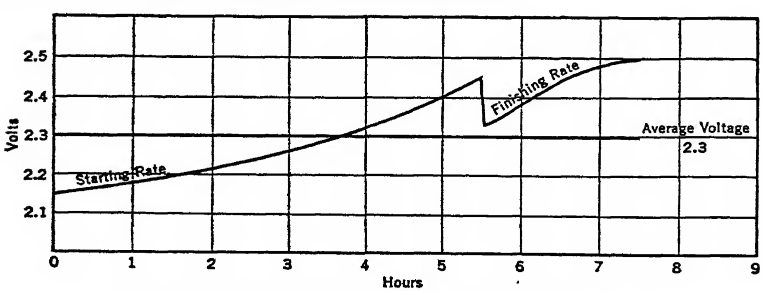

Fig. 7. Constant Current Charge. Characteristic Voltage Curve
Note: This curve is only approximate since temperature condition of the cell and other factors will cause variations from the factors shown.

Floating. A more satisfactory way to keep a battery in a fully charged condition is to maintain a constant voltage of the proper value across the battery terminals. This is known as "floating." When this is done, a low charging rate will automatically flow to the battery which will vary with varying conditions to accomplish the desired results. The proper value of the floating voltage varies with the specific gravity of the electrolyte. For 1.210 specific gravity the voltage should average 2.15 volts per cell and should not be

allowed to vary outside the limits of 2.10 and 2.20 for sustained periods. For 1.280 specific gravity the average should be 2.22 and the corresponding limits 2.17 and 2.27 volts per cell. If batteries are to be floated continuously in service, cells having low-gravity electrolyte should be used as they will have a longer useful life.

8. INSTALLATION

The essential features that require consideration in planning the details of all battery installations are: first, ample ventilation and moderate temperature; and second, accessibility of each cell for inspection and maintenance. There are other features depending on the type of battery and the nature of the service which will be discussed in later paragraphs. Ventilation is required to dissipate the oxygen and hydrogen which are given off from the battery in considerable quantities during the latter part of charge and to some extent at all times, in order to prevent the possibility of an accumulation of these gases in such proportions as form an explosive mixture and also to remove any acid spray which may be thrown into the air if open-type cells are used. It is also required to control the battery temperature, especially if there is any possibility that the battery may be subjected to high rates of charge or discharge. Accessibility to inspection and maintenance should be such as readily to permit the battery to receive such attention as is outlined under Care and Operation, page 7–24. Special attention should be given to ease of keeping electrolyte at the proper level (by adding water to the cells to replace evaporation), taking hydrometer readings, and keeping the battery clean and dry.

It is usually necessary for the battery manufacturer to make a complete detailed drawing of the battery exactly as it will be installed before he can prepare the necessary material for shipment. In the interest of both the user and the manufacturer it is very desirable that the latter be consulted in time to permit adequate provisions to be made.

GLASS JAR INSTALLATIONS. When batteries in sealed glass jars are of appreciable size they are usually installed in a separate battery room, although this is by no means a necessity. The vent plugs in the covers of modern batteries are so designed as to allow the escape of gases but to trap all electrolyte spray effectively with the result that there is no danger of escaping acid causing corrosion of any nearby metal surfaces. The batteries should be located in a clean, dry, ventilated place where they are not likely to be damaged. At least one side of each cell should be accessible from an aisle. The floor of the battery room should be of smooth concrete. The battery should be shielded from the direct rays of the sun by the use of diffusing glass in windows or skylights if necessary. The cells are mounted on wooden or steel racks whose upright members may rest on vitrified brick or tile. The racks may provide for one or more tiers of cells, but for the larger sizes of cells, single-tier racks are recommended. When the cells are arranged in more than one tier no cell should be located behind any of the uprights unless space is rigidly limited. Ample space (about 15 in.) should be allowed between the top of a cell cover and the bottom of the rack above to permit hydrometer readings.

RUBBER JAR INSTALLATIONS. Batteries assembled in rubber jars are generally used only when portability is necessary or where glass jars will not withstand the mechanical shocks to which the battery is likely to be submitted. The placing of portable batteries requires no special comment. In those installations where the battery is in motion it is necessary to provide against the battery's shifting its position and against the shocks due to sudden changes in motion. Springs have been tried and their use abandoned. Where the battery is necessarily mounted in a structure supported on flexible springs, as on a passenger automobile, the battery should be bolted solidly to the supporting structure. On electric street and industrial trucks where the body springs are relatively stiff the batteries are usually protected against jumping by some form of cleat or by holding-down bolts and against lateral or longitudinal shifting by positive mechanical stops. In locomotive and marine work no hold-downs are necessary. In no installation should the battery be wedged tightly in the compartment, as any pressure applied in this way is added to any other stresses that may be applied to the rubber jars due to weaving of the compartment or to mechanical shocks during service.

Compartments. Practically all rubber jar installations are made under conditions where the space required for the battery is also desirable for other purposes. This fact should not result in the battery's being installed in a manner which will prevent successful operation or cause excessive battery maintenance cost. Ventilation and accessibility are essential. Ample air inlets should be provided at the bottom of the compartments and outlets at the top to permit a free circulation of air. The trays should be separated from each other by at least $1/2$ in. to allow passage of air between them and to permit drainage when the battery is washed down. Rubber or porcelain spacing insulators are used for this purpose. Drainage should be provided for the wash water.

The size of the compartment should be such that no tray can move more than 1/2 in. in any direction. If blocking is required it should be placed next to the compartment walls, for if it is placed between trays, the inter-tray connectors may be subjected to strain.

In street and industrial truck service where the number of cells in series rarely exceeds 44 and where the vehicle is mounted on rubber tires no special insulation of the battery from the compartment is required, but in other services where the number of cells in series exceeds 16 and where the compartment is grounded, rubber or porcelain insulators are used between the trays and the bottom and sides of the compartment. For marine installations lead pans or water-tight lead-covered floors are sometimes provided beneath the insulated cells.

BATTERIES IN LEAD-LINED TANKS should always be installed in a specially prepared battery room, the details of which must be worked out jointly by the user and the manufacturer prior to preparation of the battery for shipment. The special features which may be required include forced ventilation system, which should be of the exhaust type with inlets near the floor at one end of the room and the exhaust outlet near the ceiling at the other end through a series of baffle plates to intercept any fine particles of electrolyte thrown into the air when the cells are gassing.

It is impossible in the confines of this section to give complete specifications for the floor construction, but such specifications based on many years of experience may be obtained from battery manufacturers. In general these specifications call for a smooth, level cement foundation surface on which one or more layers of acid-proof fabric are laid and protected by a bituminous compound mastic floor.

Provision must be made for supporting copper conductors to the battery terminals and to the end cells if the latter are used. All exposed conductors must be lead plated or painted with acid-resisting paint. Lead-covered cable in the battery room is not recommended. Supporting structure for end cell switches if used must be accurately installed, and all exposed metal must be protected against acid spray.

9. APPLICATIONS

The advantages of the storage battery as a device for storing energy, and especially electrical energy, may be enumerated as follows:

1. It is the lightest and most efficient device for storing energy in portable form, and it is therefore employed wherever energy is to be stored at one time and place for use at another.
2. Its energy is instantly available, no time being required to prepare for delivering the energy thus stored.
3. Its energy may be stored at any convenient rate and delivered at any other rate required.
4. It may be employed as a voltage transformer, storing electrical energy at one voltage and delivering it at another, by series-paralleling groups of cells.
5. The constancy of voltage of a storage battery is another characteristic which is often of pronounced importance.

Advantage is taken of one or more of these characteristics in the various commercial applications of the storage battery. The variety of applications covers such a wide range that only typical examples can be presented in this section. These examples are classified below under applications based primarily on (*a*) portability, (*b*) reliability of supply of electrical energy, and (*c*) economies effected, although in some cases there is an overlap of these classifications.

Applications Based on Portability

AUTOMOTIVE BATTERIES. Undoubtedly the largest single application of storage batteries is for the starting, lighting, and ignition of automobiles and buses. These batteries are charged automatically from a generator driven by the engine while it is running, and they supply power for the lights while the engine is shut down and for ignition and cranking when the engine is started. (For details of system as a whole see Sec. 17, Art. 28.)

The essentials for a battery for this service are ability to discharge at high rates with well-sustained voltage (low internal resistance), minimum effect from low temperature, light weight, small space, and as long battery life as is compatible with the other requirements. Pasted plate batteries are universally used. Three-cell (6-volt) batteries are the recognized standard for automobiles; 6 to 12 cell (12 to 24 volts) are used for buses. In order to reduce the weight and minimize the likelihood of freezing in cold weather, high-specific-gravity (nominal 1.280) electrolyte is used in temperate climates; lower specific

gravity (nominal 1.240) is recommended for tropical climates. The cells are generally assembled in 3-compartment rubber or asphaltic composition cases. The size of battery is usually determined by the cranking requirements, which depend on the size and number of cylinders of the engine and on the design of the cranking motor. The arrangement of the compartments in the container and the location of the battery terminals are subject to the requirements of each model of car. As the life of these batteries is considerably less than the life of the vehicle, leading battery manufacturers have provided the required variety of batteries to make replacement on any current model of automobile.

MOTIVE-POWER BATTERIES are used for the propulsion of electric street trucks, industrial trucks and tractors, and mine and industrial locomotives. These vehicles are used in short-haul or frequent-stop service which is inherent in the industrial applications cited. Long-haul, high-speed service is conceded to the gasoline truck in road work and to the trolley locomotive in mine work, but the economies which accrue with the use of battery-driven vehicles in frequent-stop, and therefore slow-speed, service seem to justify their use to a much greater extent than they have yet attained (1935).

Batteries in this service usually have sufficient capacity to perform a full day's work and are charged when the vehicle is out of service, usually at night. To a limited extent, exhausted batteries are replaced by charged ones at the end of a working shift and the vehicle kept in service for 2 or even 3 shifts a day. The essentials of a battery for this service are a minimum of space and weight, high electrical efficiency, mechanical strength to withstand road shocks, and long life in relation to the cost of purchase and maintenance. Pasted or modified pasted (Exide-Ironclad) plates are used to the total exclusion of Planté plates in this country, although the latter are used to some extent in Germany.

The cells are assembled in individual high-grade hard-rubber jars and these are in turn assembled in a number of hardwood trays arranged to suit the compartment in the vehicle. If the battery consists of more than 44 cells the trays are equipped with porcelain or rubber insulators to insulate the battery from the frame of the vehicle. The size of the battery is determined by the total amount of work to be performed and is usually specified by the truck manufacturer to conform to this work and to the characteristics of the motors he selects to drive the vehicle.

A user of motive-power batteries should exercise the same care in selecting suitable charging equipment as in selecting a suitable vehicle, and in properly charging and maintaining the battery as in inspecting and maintaining the running gear. The battery is likely to be subjected to greater hazards in the charging room than in service unless the charging equipment is properly selected and operated. Fully automatic charging equipment as described under Charging Characteristics (Modified Constant Voltage, page 7-15) is recommended by battery manufacturers.

RAILWAY TRAIN LIGHTING AND AIR CONDITIONING. Storage batteries are used in railway train lighting to supply current for lighting the cars when the train is standing or moving at slow speeds. When the train is moving above a certain speed (about 20 to 25 miles per hour) the lighting current is furnished by a generator mechanically driven from the car axle; this generator also recharges the battery automatically. In order to provide the constant voltage necessary for satisfactory lighting at variable train speeds, the generator voltage is controlled by an automatic voltage regulator. For details of these electrical systems, see Sec. 17, Art. 8.

Axle lighting systems for lighting only are generally designed for 32 volts and include 16 cells of lead-acid battery ranging in capacity from about 200 to 450 amp-hr. The much heavier loads due to air-conditioning equipment call for greater capacities up to 1000 amp-hr for 32-volt systems, and in some cases 64-volt or even 110-volt air-conditioning equipments have been adopted to reduce the size of conductors and facilitate the design of generators and control apparatus.

For the smaller sizes of batteries used for car lighting only, weight and space requirements have been considered to be of secondary importance and many Planté and modified Planté (Manchester) plates have been used and are still being maintained by many railroads although there is a tendency toward the use of flat plate and modified pasted plate (Exide-Ironclad) batteries to facilitate handling during service inspection and maintenance.

For the larger batteries required for air-conditioning, flat plate and modified pasted plates only are being used as space is not available on the car for the heavier types.

The cells are assembled in high-grade rubber jars, in hardwood trays of dimensions suitable for installing in battery boxes of dimensions standardized by the American Railway Association.

RAILWAY CONTROL BATTERIES are used to supply a continuous low-voltage source of energy for a variety of purposes on electric locomotives, on oil or gasoline-electric locomotives and rail cars, and on multiple-unit electric trains. On electric locomotives the batteries usually are operated in multiple with constant voltage motor-

generator sets to supply an unfailing source of energy for control circuits and marker and cab lights. They may also be used in connection with cab signals or automatic train control or with regenerative braking equipment when these features are embodied in the locomotive. On oil or gasoline-electric locomotives and rail cars they are also used for engine starting, air compressor operation, and generator excitation, and on the rail cars also for train lighting. On multiple-unit electric trains the present tendency is to equip each motor car with a battery and constant-voltage motor-generator for the operation of control circuits, marker and emergency car lighting, and for cab signals or automatic train control if employed. These circuits are paralleled throughout the train by means of " train lines."

The battery essentials for this service are similar to those for railway train lighting except where engine starting is required, in which case provision must be made for the high rate momentary discharges required for that purpose, and this feature will probably determine the size of the battery. Weight and space are of more importance than in train lighting owing to the larger amount of equipment required on each unit. For this reason the modified pasted plate (Exide-Ironclad) battery has found most general application. In all these applications the battery is kept practically fully charged at all times, receiving sufficient current from the generator to replace any discharge, usually of short duration, which may occur and also to replace any internal losses.

Applications Based on Reliability

STANDBY BATTERIES are installed to provide a reserve source of energy for use only in an emergency. They must therefore be kept in a state of full charge at all times. This may be done either by " floating " or by " trickle charging " (see Charging Characteristics, page 7–16).

STANDBY BATTERIES IN DIRECT-CURRENT DISTRIBUTION SYSTEMS are connected to the station bus at all times without the interposition of circuit breakers or fuses and thus are available at all times for instant use in any emergency. The batteries are so " floated " as to keep them fully charged at all times.

The middle point of the battery is connected directly to the neutral of the three-wire system: the positive and negative ends are connected to their respective buses through end cell switches by means of which the number of cells in use may be varied at will to meet the operating requirements. These switches permit the use at all times of the right number of cells to maintain the proper floating voltage across the cells in service regardless of variation in bus voltage. They also permit additional cells to be placed in circuit as may be required to control the voltage during emergency discharges. These switches are the only movable piece of apparatus used in connection with the battery at such times; their dependability is therefore of prime importance. They must offer no possibility of interrupting the discharge; they must be able to carry any currents that the battery can deliver for as long a time as the battery can deliver them; and they must be capable of being moved from point to point while carrying these currents without opening the circuit and without destructive arcing. Such switches are available having a continuous carrying capacity up to 10,000 amp and a 6-min carrying capacity of 40,000 amp. Two or more of these switches may be operated in multiple when more carrying capacity is required.

Charging. To charge these batteries after an emergency discharge, they are usually disconnected from the bus and charged from a motor-generator or rotary converter whose voltage is raised as may be required until its maximum voltage is reached, after which a booster generator is connected into the circuit to raise the voltage further to the value required to complete the charge. This booster is usually a three-unit motor-generator set having one motor which takes its power from the station bus and two generators one for each side of the battery, thus permitting independent control of the charge of the two halves to compensate for any inequality in discharge which may have occurred. The charging is done at a time when emergency protection is of minor importance.

Type of Battery. Direct-current distribution systems are largely confined to the more densely populated sections of the larger cities where real estate is very valuable. The space occupied by these batteries is therefore of great importance, and they are required to do very little work during their lifetime. Both these reasons indicate that the flat plate pasted type of battery should be used, and this type has been installed exclusively in recent years although many of the older modified Planté (Manchester) batteries are still in service.

Size of Batteries. As the purpose of these batteries is to prevent a failure of power on the distribution system they must be of sufficient capacity to carry the maximum load for which the station is designed for a long enough period to permit re-establishment of normal source of power. The length of this interval is largely a matter of judgment and varies with different stations, but 20-min protection for the maximum load is usually

considered to be sufficient. When the rate and duration of the discharge are known the size of cells required is easily determined from data similar to those shown in Fig. 3, page 7–13.

The number of cells is determined from the final voltage per cell at the maximum discharge rate and the minimum allowable voltage. The number of end cells must be sufficient to permit enough cells to be cut out of circuit to allow proper floating when the station bus voltage is at its minimum value. In order to keep the end cell switches as small as possible and to reduce the amount of copper required for connections between these switches and the end cells, it is now customary to use groups of 2 end cells each between switch contacts within the floating range and groups of 3 or 4 cells between contacts for those end cells which are employed only to maintain voltage during emergency discharges.

STANDBY BATTERIES FOR EMERGENCY LIGHTING AND POWER are installed to accomplish the same general purposes as the larger batteries used with central station direct-current distribution systems but the installations are so much smaller and the local conditions so different as to require very different treatment.

Emergency Lighting Batteries, in some places required by law or ordinance, are employed in theaters, schools, hospitals, banks, etc., to provide a second source of power which is automatically applied to selected circuits in case of failure of the normal power and thus maintain illumination in locations such as corridors and exits and in special locations such as operating rooms in hospitals, banking rooms and vaults in banks, etc. These batteries must be floated or trickle-charged from the normal source of power, but usually they are not operatively connected to the emergency circuits except in case of a power failure when an automatic switch disconnects the emergency circuits from the normal supply and connects them to the battery. In some cases automatic return to normal connections on return of power, and automatic recharging of the battery, are provided. Where the normal power is alternating current, the battery is trickle-charged by means of a small rectifier and recharged by a rectifier or motor-generator set. Where the normal power is direct current, the battery is usually trickle-charged from the main power supply in a manner similar to that described below under Emergency Power Batteries.

It is impossible within the limits of this section to discuss the details of the electrical connections used in this service as they must differ widely depending on the nature of the normal supply, that is, whether it is single-phase 2 or 3 wire, 2-phase 4 or 5 wire, or 3-phase 3 or 4 wire. These details have been worked out, however, and suitable apparatus is available for any of these conditions. Ordinarily no provision is made for the control of voltage during emergency discharges. A suitable number of cells is used, generally 60 for a nominal 115-volt circuit, and the voltage is allowed to fall as the discharge progresses. If a certain minimum voltage must be maintained a size of cell is selected large enough to meet the requirements.

Type of Battery. As these batteries are not subject to daily work, the pasted plate type has been most generally used, particularly where the installation has been required by law or ordinance, when the lower first cost has been the deciding factor.

Emergency Power Batteries are employed in industrial plants to insure continuity of power for such a period as is necessary to prevent loss of material in process in case of power failure, as in glass mills to clear the mill before the glass cools or in steel mills to right a ladle which is pouring molten metal, etc. The motors to be protected must be of direct-current types, although there is some prospect that the recent development in "inverters" may soon make this protection available for alternating-current motors. In direct-current service the batteries are trickle-charged in two multiple circuits through resistors from the normal supply circuit and recharged in the same manner through other resistors. In event of a power failure a low-voltage relay drops, making contacts which close a contactor connecting the two halves of the battery in series and trips a contactor which disconnects the protected circuit from the incoming power circuit. Two trickle-charge resistors are allowed to remain in circuit as the energy lost in them during the emergency is negligible; if, however, the battery is receiving a high rate charge, the circuit through the charging reistors is automatically opened. If the low-voltage relay will pick up on return of normal power, normal operation will be resumed automatically when the power returns. Connections for recharging the battery are usually made manually.

In some instances due to local conditions it is considered preferable to float and recharge the battery from a separate motor-generator set in order that the battery may be entirely isolated from shop circuit under normal conditions. In such a case a simple throw-over switch to disconnect the protected circuit from the shop supply and connect it to the battery is all that is required for automatic protection.

Type of Battery. Pasted plate batteries are ordinarily used for strictly emergency

protection, but in some cases where the battery is installed primarily for this purpose it may also be employed to perform some work during normal operation. For such applications see "Floated Working Batteries."

FLOATED WORKING BATTERIES. There are many electrical installations which justify the use of a standby battery for emergency protection but which also present opportunities for effecting economies if the battery is allowed to do some work during normal operation. These batteries are permanently connected to the circuits which they protect. During normal operation, an external source of power, usually a motor-generator set or rectifier, is also connected to the circuit and in multiple with the battery. The voltage across the circuit is maintained by the generator at an average value suitable for "floating" the battery. The generator delivers to the circuit the average power requirements, and the battery discharges automatically at times of high load and recharges automatically when the load is below the average. The total amount of the work done by the battery per day during normal operation is usually relatively small, and the battery is kept in a state of nearly full charge and therefore always available for emergency use. In some applications the battery may become appreciably discharged at times during normal operation; when this is contemplated the battery must have enough capacity to perform both services.

Type of Battery. In this service the life of the battery depends largely on the accuracy with which the "floating" voltage is maintained but in some cases on the total amount of work which the battery has to perform. If local conditions are such that the "floating" voltage may be erratic or if a considerable amount of work is required while floating, Planté, modified Planté (Manchester), or modified pasted (Exide-Ironclad) batteries are selected. If the floating voltage can be well maintained and the amount of work is small, flat pasted plate batteries are used.

CONTROL BUS BATTERIES are employed in practically all generating and substations to assure a continuous source of power in any emergency for operation of circuit breakers and other remote-controlled apparatus and also for emergency lights. The control bus is usually completely isolated from station buses so as not to be affected by any disturbance which may occur on them. The battery is permanently connected to this bus at all times, and a small motor-generator set (or rectifier) is provided to carry the continuous load, composed principally of indicating lights, and to keep the battery fully charged. The emergency lights ordinarily receive their energy from the "house" bus, but in case of failure of that bus the emergency light circuit is automatically disconnected from the house bus and connected to the control bus by a throw-over switch. The normal load on the control bus is thus very small, as the indicating lamps consume only about 0.1 amp or less for each oil circuit breaker, therefore a small motor-generator set can be used provided the battery is allowed to supply the high momentary loads required for operation of the circuit breakers. This is readily accomplished by employing a generator whose load-voltage characteristics are such as to present a sufficient droop in voltage at overload as to cause the battery to take practically all the excess demand. The design of circuit-breaker mechanisms has been standardized by N.E.M.A. for the operation of nominal 125-volt mechanisms within the limits of 130 to 90 volts for closing and 140 to 70 volts for tripping (for nominal 250-volt mechanisms these values are doubled). For 125-volt mechanisms 60 cells has been standardized as well as an allowance of 15 volts for copper drop between the battery terminals and the circuit-breaker mechanisms. The battery must therefore be of such a size as to be able to deliver the required loads with the voltage at its terminals not below 105 volts or an average of 1.75 volts per cell for 60 cells. Battery manufacturers publish in their trade catalogs the ratings of their cells to this voltage. The correct floating voltage for 60 cells, using 1.210 specific gravity electrolyte, is 129 volts, which is therefore the normal operating voltage of the control bus. The generator must therefore deliver this voltage when carrying the normal control bus load. In order to charge the battery after an emergency discharge, the generator voltage is raised from time to time as necessary but not above 140 volts, which is the maximum voltage permissible on the circuit-breaker mechanisms and indicating lamps. In order to prevent excessive overload on the generator when heavy demands are thrown on the bus for closing oil circuit breakers, the generator voltage must fall to 105 volts in order to permit the battery to take a large part of the increased load. Specially designed shunt-wound generators are extensively used for this purpose in manually operated stations where there are no prolonged changes in load on the control bus. In unattended stations where holding coils and relays may introduce prolonged changes in load, these changes introduce changes in the voltage of the control bus due to the drooping characteristics of the shunt generator which interfere with the proper floating of the battery unless artificial loads are introduced when these variable loads are disconnected. In order to avoid this complication, generators have been designed and are now available which have a very flat

voltage characteristic at all loads up to a predetermined point and a sharply drooping characteristic at higher loads. Such a generator maintains a favorable floating voltage during normal operation even under moderately variable loads but throws all excess load due to circuit-breaker operation onto the battery.

Size of Battery. In an emergency the battery must be able to carry the indicating lamp load throughout the duration of any loss of normal power. It is now common practice to consider a 12-hr interruption as possible in manually operated stations and 24 hr in non-attended stations. Emergency lighting protection is, however, usually provided for a period of 1 to 3 hr only. In addition to carrying these loads the battery must be able to deliver the current required for circuit-breaker operation *at any time* during the emergency. Trade catalogs give methods of approximating the size of battery required to meet any such desired conditions, but it is usually good practice to submit the conditions to manufacturers for their recommendations.

RAILWAY SIGNALING BATTERIES. Storage batteries are used extensively in the so-called a-c floating battery system for railway automatic signaling. The function of the battery is to supply a continuous source of energy for operation of the signaling devices in case of failure of either the power supply or the rectifier and also to maintain a constant voltage on the signal circuits under varying current demands. At each signal installation a battery is operated in multiple with a rectifier which is adjusted to maintain the proper voltage across the battery and to supply the average load required for operation of the necessary relays and signal lights. The general method of operation is similar to that described above. The rectifiers have a drooping characteristic which throws heavy demands for current on the battery which is automatically restored during times of lighter load. The batteries have sufficient capacity to carry the entire load between periods of inspection, if the normal supply of current in the rectifier should fail.

YACHT AND MOTORSHIP BATTERIES. Floated batteries on Diesel-engine-driven yachts and motorships are used in much the same way as has already been described. Their most important function is to assure a reliable supply of energy at all times for lights and for the operation of important electrically operated auxiliaries such as steering gears, winches, pumps, radio, etc. On the larger yachts they also furnish all necessary auxiliary power and light when the yacht is at anchor and the noise and vibration of a running engine are objectionable. They are also used to relieve the auxiliary engine generator sets of fluctuations in load caused by the simultaneous operation of the auxiliaries and so permit the use of smaller engine-generator sets and effect saving in cost, weight, and operating expenses as well as adding to safety and convenience. Fifty-six cell batteries are ordinarily used for nominal 115-volt installations, and the floating voltage is 125 volts. When necessary to recharge the battery the generator voltage is raised as may be required to not over 135 volts, which is permissible for the auxiliary motor equipment. To protect the lights and some of the more sensitive auxiliaries such as gyroscopic compass and radio equipment, automatic voltage regulators are employed in those circuits. The generators must be able to deliver full load at 112 to 135 volts, and, to assure stability of operation of the generators and battery in multiple, the generator voltage characteristic should under no operating condition show a rise in voltage with increasing load. With this condition met the voltage characteristic will necessarily be drooping at higher loads. This fact together with the drop in speed of the Diesel engine under overloads causes the battery to relieve the engine of excessive loads and permits the use of smaller auxiliary generating sets which operate at better load factors. Pasted or modified pasted plates in 1.280 specific gravity are generally used to economize in space and weight.

DRAWBRIDGE BATTERIES may be taken as typical of applications where protection is required against failure of the normal power supply and where the average load is low but short-time demands are heavy. The normal source of power may be from an internal-combustion engine generator set or from a public utility whose power bills include a maximum demand charge. In either case the battery supplies energy for the operation of the draw and so reduces the demand on the normal source of supply and improves the economy of operation as well as providing emergency protection. When the heavy load demands are fairly frequent, the battery is floated across the generator in the same manner as described under Yacht and Motorship batteries, above, except that the generator may have a more sharply drooping characteristic in order to throw a greater percentage of the load on the battery and thus maintain a more nearly constant load on the generator. If the heavy loads are sufficiently infrequent greater economy may be effected by cycle operation of the battery, that is, by using the battery alone for normal operation and running the generator only when it is necessary to recharge the battery.

TELEPHONE BATTERIES. The telephone companies rank among the largest users of storage batteries as they employ one or more batteries in practically every main and branch exchange. These batteries are always so operated as to leave a sufficient

reserve capacity to provide for continuity of service if the normal source of power should fail. They are, however, used in many cases as the sole source of power during intervals of light demand, this use depending on local operating conditions and the type of equipment employed. The batteries are floated at all times when not carrying the load or being charged.

CYCLED BATTERIES are used in some services where continuity of service is of such importance that it is desirable to have the circuit entirely isolated in order that it may not be affected by any external disturbances.

10. CARE AND OPERATION

The essential features of general care of storage batteries are simple and few, but they are *essential*. They are briefly as follows:

a. Keep the battery *clean* and *dry*.

b. Add water (which has been approved by the manufacturer) from time to time to keep the level of the electrolyte above the top of the separators.

c. Never add electrolyte or acid except to replace a loss known to be due to spillage. The added acid should then be of the same specific gravity as that in adjacent cells.

d. Never allow any "special solutions," powders, jellies, or any metals or other foreign matter to get into the cells.

e. Stop discharge, except in emergency, *before* the voltage falls too low for satisfactory operation.

f. Charge at rates low enough to keep the cell temperature below 45 deg cent (113 deg fahr), and while the cells are gassing never charge at rates higher than allowed by the manufacturer.

NOTE: All manufacturers furnish complete instructions for the care and operation of their different types of batteries. To follow these instructions systematically requires little time and work, which pay for themselves many times in prolonging the life of the battery and in assuring reliable and trouble-free performance.

Avoid excessive overcharge in ampere-hours, even if the rate of charge is low enough to avoid excessive temperature and gassing.

ALKALINE-TYPE STORAGE BATTERIES

By E. W. Allen and F. Brehme

Alkaline storage batteries are so termed because of the fact that their electrolyte is an alkaline solution (either potassium or sodium hydroxide). Alkaline batteries of present commercial manufacture employ active materials of either the nickel-iron or the nickel-iron-cadmium combination. Such batteries are the Alconum, Alkum, Britannia, Deac, Edison, Jungner, Nife, and Saft, all of foreign manufacture except the Edison. An alkaline battery (Drumm) using the nickel-zinc principle has been in experimental use in Ireland for some years. The nickel-iron-alkaline storage battery was invented by Edison in 1901, this being the only alkaline battery of commercial importance in this country.

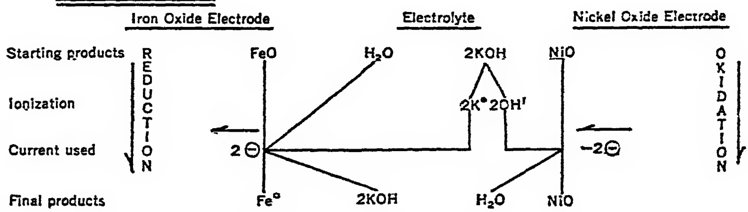
The more important uses to which Edison alkaline storage batteries are applied include: electric street trucks, electric industrial trucks and tractors, storage battery mine and industrial locomotives, railway carlighting and air conditioning, railway signal systems, multiple unit control, marine services, isolated lighting plants, emergency lighting, time clocks, police and fire alarm systems, oil circuit-breaker control, miners' safety cap lamps, airway beacons, and telephone service.

11. THEORY AND ELECTROCHEMICAL REACTIONS

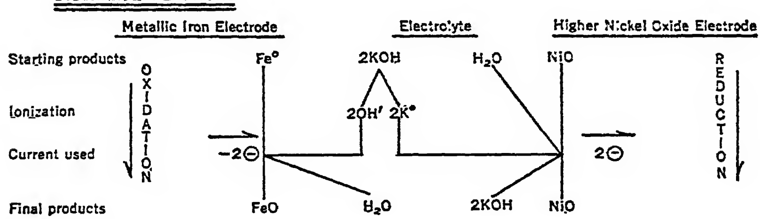
The fundamental principle of the Edison storage battery is the oxidation and reduction of metals in an electrolyte which neither combines with nor dissolves either the metals or their oxides, and which, notwithstanding its decomposition by the action of the battery,

is immediately reformed in equal quantity and is therefore a practically constant element without change of density or conductivity over long periods of time. The active materials being insoluble in the electrolyte, no chemical deterioration can take place. The chemical reactions in charging the Edison storage battery are: (1) the oxidation from a lower to a higher oxide of nickel in the positive plate, and (2) the reduction from ferrous oxide to metallic iron in the negative plate. The oxidation and reduction are performed by the oxygen and hydrogen set free at the respective poles by the electrolytic decomposition of water during charge. The charging of the positive plate is therefore simply a process of increasing the proportion of oxygen to nickel. The discharge of the cell is merely the reverse of this process, the hydrogen reducing the higher oxides of nickel to lower oxides and the oxygen oxidizing the iron to ferrous oxide. The electrolyte is an aqueous solution of potassium and lithium hydroxide and does not at any stage cause a disintegration or solution of the active materials. Its specific gravity does not change appreciably on charge or on discharge. The changes that occur when an Edison nickel-iron-alkaline cell is charged and subsequently discharged are represented by the following equations:

CHARGE REACTIONS



DISCHARGE REACTIONS



12. DESIGN AND CONSTRUCTION

POSITIVE PLATE. The positive plate consists of a nickel-plated steel grid holding nickel-plated steel tubes which contain the positive active material. When inserted in the tubes the active material is in the form of nickel hydrate, but this changes to an oxide of nickel after the formation treatment described later. In order to give the electrolyte free access to the active material the tubes have numerous perforations. To obtain improved conductivity the active material is alternated with layers of pure nickel flake at the time it is stamped into the tubes. The tubes are reinforced by eight seamless steel rings, equi-distantly spaced. The tubes are mounted on the positive grid and forced into permanent position under a pressure of 40 tons.

NEGATIVE PLATE. The negative plate is of similar construction to the positive except that a finely divided oxide of iron is employed as active material and is contained in rectangular perforated steel pockets instead of tubes. The pockets are forced into place under hydraulic pressure of 120 tons. The grid and pockets, like the positive grid and tubes, are of nickel-plated steel.

PLATE ASSEMBLY. The positive and negative plates are assembled into positive and negative plate groups (see Fig. 1). This is accomplished by passing a steel connecting rod through a hole in the top of each plate. Steel washers are employed to obtain proper spacing, the middle spacer being the base of the pole piece. A lock washer and nut are drawn up tight at each end of the connecting rod, binding the plate groups firmly together. All washers, nuts, connecting rods, and terminal posts, like the plates, are of nickel-plated steel.

The plate groups are assembled into complete elements by intermeshing the plates

so they are alternately negative and positive. The negative group always contains one more plate than the positive so that both outside plates are negative. Adjacent positive and negative plates are insulated from each other by the use of vertical hard-rubber pins running their entire length. Thin rubber sheets insulate the outside negatives from the sides of the container. The edges of the plates are insulated from the bottom and from the other sides of the container by hard-rubber frames. These frames also serve the

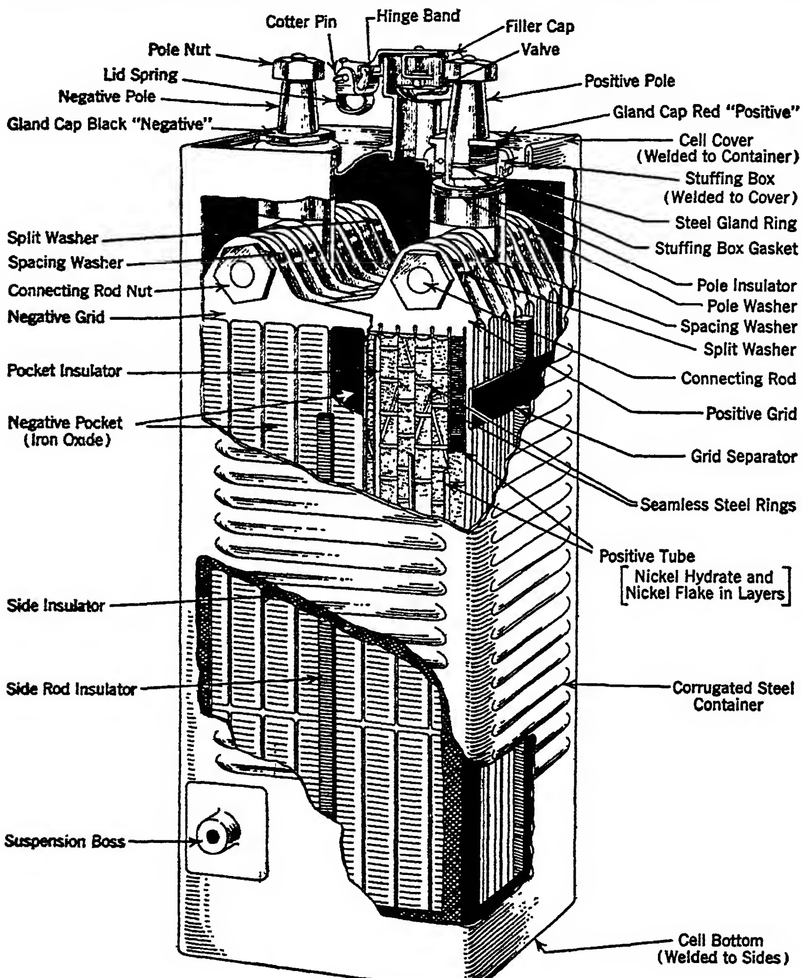


FIG. 1. Plate Assembly of Edison Storage Battery

purpose of separating the plates, holding them in correct alignment, and are so designed as to permit free circulation of the electrolyte.

CONTAINER. Caustic potash does not attack steel, and this fact is taken advantage of in the Edison nickel-iron-alkaline cell in order to obtain the strength, durability, and light weight of steel in the container as well as in the elements. The container, like the elements, is made of nickel-plated steel with all seams welded. For the larger sizes, cell containers are corrugated to increase strength and heat radiation. After the elements are inserted, the cell cover, also of nickel-plated steel, is welded in place. Soft rubber bushings, expanded by steel rings and hard-rubber gland caps, insulate the pole pieces

where they project through the cover of the cell and provide an air- and liquid-tight packing. The gland caps are colored red for the positive and black for the negative.

Projecting from the cell cover is the filler body on which is mounted a hinged filler cap. The filler cap is held positively in either a completely open or completely closed position by means of a flat steel spring. Suspended from the underside of the filler cap is a hard-rubber hemispherical valve which seats by gravity when the cap is closed. This valve, while permitting gas to escape, excludes the external air and reduces evaporation.

ELECTROCHEMICAL FORMATION. The electrolyte is then added and brought to a level of from $1/2$ in. to 3 in. above plate tops depending upon the type of cell. The electrolyte consists of a solution of potassium hydroxide in water. A small quantity of lithium hydroxide is added which increases the capacity and life of the cell. The electrolyte has a normal specific gravity of 1.200 to 1.210 at 60 deg fahr. Throughout the useful life of the cell, owing to spillage, loss through gassing and the introduction of impurities through flushing (i.e., addition of water to make up for losses due to evaporation and electrolysis) the electrolyte gradually weakens and may need renewal one or more times. When the specific gravity reaches a low limit of 1.160 at 60 deg fahr the electrolyte should be renewed. Standard renewal solution obtained from the manufacturer must be used.

When the assembly is completed and the cell filled with electrolyte, it is given several cycles of charge and discharge. This is known as the formation treatment and is for the purpose of stabilizing the electrochemical characteristics of the cell. It is continued until tests show normal operation and an excess over rated capacity. All cells are coated with a heavy insulating paint (Esbalite) after which a protective film of rosin petroleum jelly (Esbaline) is applied to the cell tops.

ANNEALING PROCESS. Before assembly all nickel-plated steel parts are subjected to high temperature in an atmosphere of hydrogen. During this operation the nickel plating is actually annealed to the steel, becoming an integral part of its surface.

BATTERY ASSEMBLY. Nickel-iron-alkaline cells are assembled into batteries in painted hardwood trays to facilitate handling (see Fig. 2). Steel bosses, previously spot welded to the sides of the cell containers, fit into hard-rubber buttons recessed in the tray slats. This type of assembly supports each cell in its proper place and insulates it from the tray and from adjacent cells. Tray assemblies are available in from 1 to 20 cells per tray, depending upon the size of the cells and the requirements of the installation. The usual application uses trays having somewhere between 3 and 8 cells.

The tops of the pole pieces are threaded. Immediately below they are tapered to

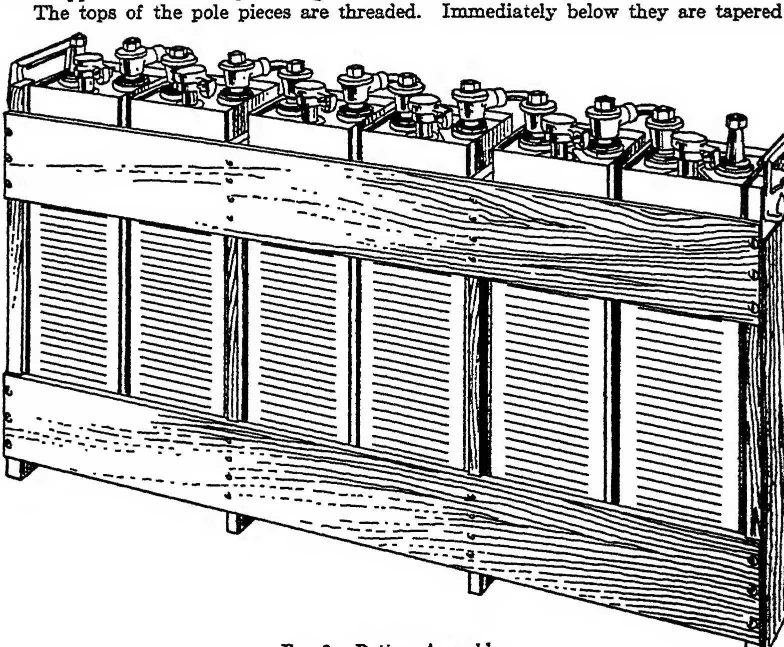

Fig. 2. Battery Assembly

fit the lugs of the intercell and intertray connectors. The connector lugs are steel forgings bored to fit the taper on the pole pieces and are swedged upon heavy copper connecting links. Connectors are secured by tightening down nuts and are removed by means of a small jack after the nut is loosened. All lugs, links, and nuts are nickel plated.

TYPES AND SIZES. The type of cell is determined by the size of the positive tubes and by the number of tubes per plate. The type is indicated by a letter, present manufacture including A, B, C, F, G, L, and N types. A, B, C, and F type positive plates have tubes $1/4$ in. in diameter and a little over 4 in. long. Tubes of this size have a normal discharge rate of $1/4$ amp per tube for 5 hr. The A type plate contains two rows of 15 tubes each, the B type plate contains one row of 15 tubes, the C type plate contains three rows of 15 tubes each, and the F type plate one row of 4 tubes. The N type plate contains one row of 7 tubes 3 in. long and $1/4$ in. in diameter. The G and L type positive plates have tubes $3/16$ in. in diameter and a little over 4 in. long. Tubes of this size have a normal discharge rate of $3/16$ amp per tube for 3 $1/3$ hr. Two rows of 20 tubes each are used in the G type positive plate and one row of 10 tubes in the L type positive plate.

The sizes of the various types of cells are determined by the number of positive plates. This is indicated by a number following the type letter. For example, a cell containing 4 A type positive plates is designated A-4; a cell containing 6 B type positive plates is designated B-6. Type and size designation is stamped on the cover of each cell. In duty such as railway carlighting and air conditioning where regular flushing is not always practicable, containers of extra height or both extra height and width are often used in order to increase the relative quantity of electrolyte. Such cells are designated as high and high wide types, the letters H and HW being added to the designation stamped on the cell covers: as A4H, A4HW, etc.

Table 1. Ratings and Weights

* Ratings based on 5-hr discharge for A, B, C, and N types, and on 3 1/3-hr discharge for G and L types; average voltage 1.20.

† Pounds per cell, completely assembled, including trays, connectors, electrolyte, etc.

NOTE.—The letter "H" indicates high-type cells; these cells have the same characteristics as the standard-type cells but are built higher so as to hold more electrolyte. They are recommended for use where longer flushing intervals are desirable. Some of the A type sizes are available in an HW (high wide) container for railway carlighting service exclusively.

* When figuring battery dimensions, it is good practice to add 1 in. to filler cap open height so as to insure sufficient clearance. Also for easy fitting, add 1/8 in. to length and width dimensions of each tray.

† For N2 cells, dual trays are supplied up to 20 cells; width is 7 in. and length is same as for single trays.

13. ELECTRICAL CHARACTERISTICS

Charging

Charging requires direct current. When only alternating current is available, a suitable motor-generator set, mercury-arc rectifier, or other current-rectifying device must be used. Specific gravity readings are no indication of the state of charge and are therefore not necessary except as an indication of when solution should be renewed. Although Edison batteries may be successfully charged at various rates it is first necessary to establish a standard or normal rate for reference purposes. The normal rate of charge has been chosen by the manufacturer in such a way that for an output of approximately the rated number of ampere-hours, when discharging at normal rate, the efficiency is higher than for a charge rate which is considerably higher or lower than the normal. The normal charge rate for the different types and sizes of Edison batteries is the same as the amperes shown in the tabulation given under the previous heading, Ratings and Weights.

CONSTANT CURRENT CHARGING. In constant current charging, the charge rate is held fairly constant throughout the charge, and this rate should approximate the normal rate. The battery voltage will rise from approximately 1.50 to 1.85 volts per cell during the charge, and adjustments will need to be made from time to time to maintain the current rate. A voltage of at least 1.85 volts per cell must be available at battery terminals in order to complete the charge at normal rate. Voltage regulation can be obtained by use of a variable resistance in series with the battery or by variation of the field rheostat of the charging generator if an individual motor-generator set is used. The length of time required to charge will depend upon the extent to which the battery was previously discharged, the battery being considered fully charged when the terminal voltage ceases to rise for a period of 30 minutes during charge with constant current flowing.

MODIFIED CONSTANT POTENTIAL CHARGING. Modified constant potential is taper current charging, the current during the first part of charge is higher than the

normal rate; during charge the rate decreases until at the end of charge the rate is less than normal. With this method a fixed and permanent resistance is inserted in series with the battery and no adjustments are made during charge. A charging line voltage of at least 1.84 volts per cell must be available and maintained throughout the charge, but higher voltages may be used. The higher the voltage the more closely will the taper of the charging rate approach the straight constant current method as a limit. When using the proper fixed resistance, the following charge rates will obtain for various charging voltages:

Line volts per cell	1.84	1.90	1.95	2.00	2.10	2.20
Initial rate (% normal)	165	155	147	140	128	124
Final rate (% normal)	65	70	74	78	84	86

In each case, the result will be to average normal rate for a complete charge. The length of charge required will be dependent upon the state of charge of the battery when it was placed on charge. The object is to put back into the battery 25 per cent more ampere-hours than have been taken out. The state of charge can be determined by the use of an ampere-hour meter (or by a special device made by the battery manufacturer known as an Edison charge test fork).

The following formula shows how to determine the proper fixed series resistance mentioned above: $V - (1.69 \times N)/A = R$, where V is the voltage of the charging line, N is the number of cells in series in the battery, A is the normal ampere rate of the battery, and R is the ohms fixed resistance required. Example: with a 45-volt charging line, what resistance is required to charge a 24-cell A8 Edison battery? Answer: 45 volts − (1.69 × 24 cells)/60 amperes = 0.074 ohm. It is to be noted that the series resistance thus calculated is the total resistance required between the line and the battery; the charging leads, switches, etc., will form part of the resistance, the balance to be added. The current-carrying capacity of the resistance should be sufficient to take care of the initial current rate which will flow into the battery at the beginning of charge. See table above.

BOOST CHARGING. Although not recommended as a regular practice occasional emergencies will require that the batteries be charged faster than ordinarily, which necessitates higher rates. Permissible ampere rates are: 1 hr at two times normal rate, or 1/2 hr at three times normal, or 1/4 hr at four times normal, or 5 min at five times normal. Frothing at the filler cap, or electrolyte temperatures in excess of 115 deg fahr, are indications that boosting has been carried too far and it should be discontinued at once.

LOW RATE CHARGING. Where discharge requirements are such that a low constant rate is used, or where intermittent or variable rates are such as to average a low value over a given period of time, then charge rates may be less than normal. In these cases, the charge rate may be as little as 1.2 times the average discharge rate. It must be remembered, however, that it will still be necessary to put back into the battery 25 per cent more ampere-hours than have been used on discharge. The length of time for a complete charge will thus be longer because the current is put in more slowly.

TRICKLE CHARGING. Edison batteries may be trickle-charged when used in such applications where trickle charging is ordinarily employed. The voltage required will normally be between 1.50 and 1.55 per cell depending upon the temperature, age of the battery, the rate used, and other factors. The proper trickling rate for any given installation can be approximated by the following formula: $(C \times 0.16) + (D \times 1.10)/(24 - H) = A$, where C is the rated ampere-hour capacity of the battery, D is the ampere-

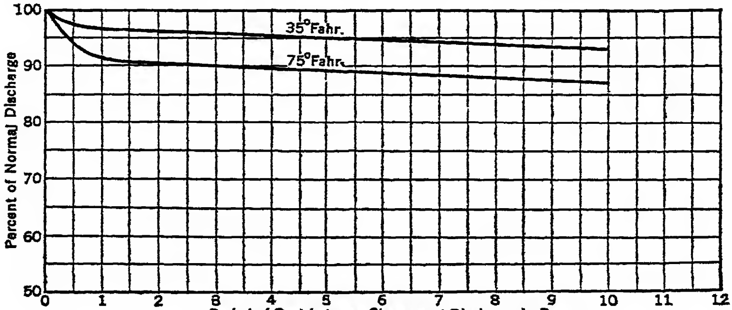

FIG. 3. Loss of Charge when Idle

hours used per day, H is the total hours of discharge per day, and A is the trickle charge rate in amperes.

RETENTION OF CHARGE. The curve of Fig. 3 shows the loss of charge when standing idle following a complete charge.

Discharge Characteristics

At the normal rating, Edison cells have an average voltage of 1.20 volts. However, like all other storage batteries, the voltage will be less when discharged at high ampere rates, and when discharged at low rates the voltage characteristics are better than normal. The curves of Fig. 4 show the discharge voltage characteristics of an Edison cell in good condition when discharged continuously at various rates. For instance, suppose that it is desired to know what voltage to expect from a 30-cell type A8 Edison battery when discharging at 120 amp and after it had been thus discharging for 1 1/2 hr. The ampere-

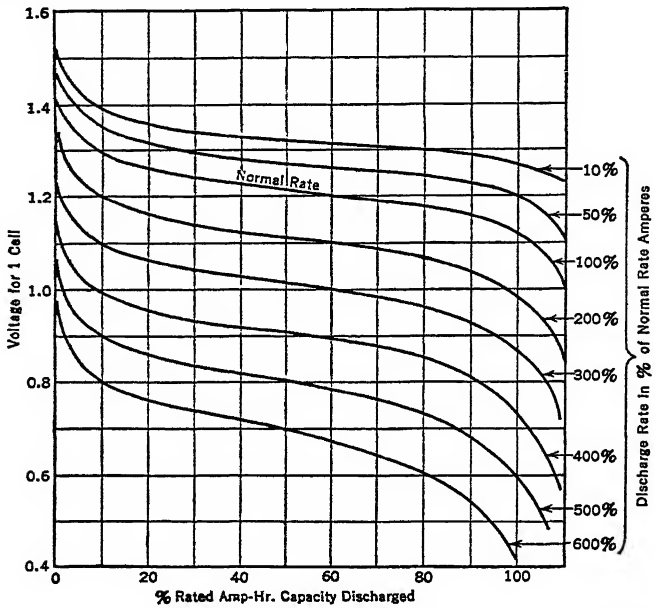

FIG. 4. Edison Alkaline Storage Battery Discharge Voltage at Battery Terminals (Note: Allowance has been made for losses in connectors and jumpers)

hours taken out would be ($120 \times 1\ 1/2$) 180, and since the rated capacity (see Table 1) of an A8 type cell is 300, then the cell would be in a condition of 60 per cent discharged. The 120-amp discharge rate is twice the normal (60 amp) rating of an A8; therefore by referring to the 200 per cent normal discharge curve at the point of being 60 per cent discharged the voltage is found to be 1.10 per cell; therefore a 30-cell type A8 Edison battery in good condition would deliver 33 volts at the end of 1 1/2 hr of discharge at a 120-amp rate.

CAPACITY. The capacity of a nickel-iron-alkaline cell depends upon the number and type of its positive plates. For ready reference the ampere-hour capacities are shown in Table 1. Normal watthour capacity is the normal ampere-hour capacity multiplied by the average voltage. The rated capacity is based on a 5-hr discharge to 1 volt per cell for A, B, C, F, and N types, and on a 3 1/3-hr discharge to 1 volt per cell for G and L types. These values are on the basis of discharge at normal rate. It will be noted from the above discharge curves that there is no appreciable difference in ampere-hour capacity at several times the normal discharge rate because the characteristics of the cell do not necessitate a limit to the final voltage. The cell may be discharged to zero voltage without injury.

During the first 125 duty cycles the capacity increases gradually above its initial capacity. This increase may be as great as 15 per cent above the rated capacity. After this the capacity gradually decreases. When the specific gravity of the electrolyte drops

to 1.160 at 60 deg fahr it is renewed, immediately following which another increase in capacity occurs. This is usually the point of maximum capacity during the life of the cell. In most services the useful life is considered at an end when the ampere-hour capacity drops to less than 80 per cent of rated. The Edison alkaline cell maintains its rated capacity for the greater part of its normal life.

EFFICIENCY. Although under laboratory conditions, ampere-hour efficiencies ranging up to 95 per cent can be obtained, the practical operating ampere-hour efficiency of an Edison alkaline battery is approximately 80 per cent, thus requiring an input of about 25 per cent more than has been taken out on discharge. The laboratory voltage efficiency ranges up to 80 per cent, but this has no meaning as far as practical operation is concerned because the voltage efficiency of a battery installation will depend upon the methods of charging used, the charging line losses, the efficiency of the charging current source, etc. For any given installation, the efficiency of battery operation can be computed by determining the watthour input required at the service meter as against the watthours obtained from the battery on discharge. However, in those services where alkaline batteries are applied, the cost of charging batteries is usually a relatively small item in the total cost

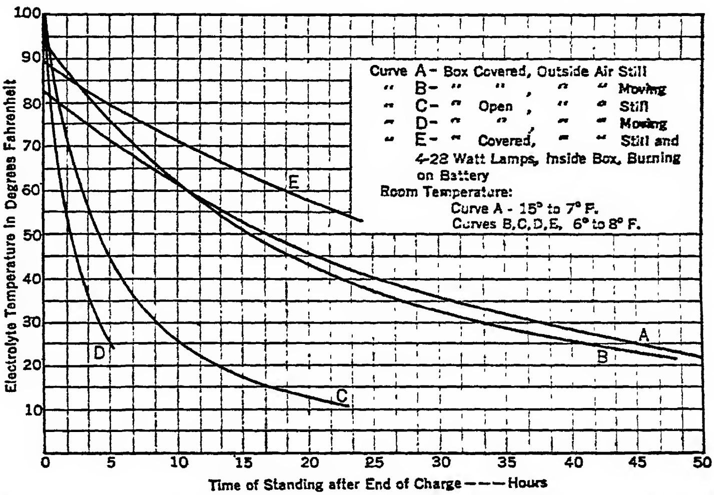

FIG. 5. Rate of Cooling of Electrolyte of Standard Battery of 40 Type A-6 Cells, Housed in a Regular Battery Box. Battery was charged at normal rate (45 amperes) with the air temperature at about 65° F. and then allowed to stand idle to cool under various conditions as noted above. Test made by Electrical Testing Laboratories

of battery operation, and a comparatively wide range in the efficiency of batteries makes but a slight difference in total operating cost.

TEMPERATURES. High temperatures are to be avoided as all batteries are damaged by high electrolyte temperatures. It is recommended that Edison alkaline batteries be operated at temperatures under 115 deg fahr. To assist in holding down electrolyte temperatures of Edison batteries used in heavy duty service, such as motive power, the battery compartments should have provisions for ventilation in warm weather. Evenly spaced slots or holes should be made at the top and in the bottom of the battery box; top ventilation is usually placed on the sides of the box as close to the top as possible. Depending on the severity of the work and on the climate, a certain range of ventilation has been found by experience to be satisfactory, and may be determined by the following formula: $F \times N \times C = A$, where F is a factor of 0.01 to 0.02 depending on severity of condition, N is the number of cells in the battery, C is the rated ampere-hour capacity of the battery, and A is the area in square inches of ventilation required. This amount of square inch ventilation should be applied to the top, and a like amount to the bottom of the battery compartment. Adequate ventilation will result in both better operating performance and longer battery life.

Low temperatures will not harm an Edison alkaline cell. At an electrolyte temperature of approximately -20 deg fahr the electrolyte will have become slushily crystallized but it will not freeze hard and cause injury. The capacity of the cell decreases as the

electrolyte temperature drops. The extent of the decrease varies considerably with the rate of discharge, being relatively small at low rates and large at high rates. At normal rate a reduction of electrolyte temperature from 115 to 50 deg fahr will reduce the capacity 10 per cent. Below 50 deg fahr the reduction in capacity is important. The electrolyte temperature of a working cell is always higher than the atmospheric temperature due to the heat generated by the passage of current. The amount of heat varies with the rate of charge and discharge, being relatively small at low rates and larger at high rates. In practice, electrolyte temperatures in a cell discharging at normal rate do not generally fall below 60 deg fahr. Under cold weather conditions battery compartments should be closed, and under extreme conditions it is sometimes good practice to insulate the compartment. Even though air temperatures may be very low, it takes a long time for electrolyte temperatures to drop to that of the outside air if the battery compartment is closed, as the curves of Fig. 5 show.

14. LIFE

The life of the cell is from 7 to 20 years, depending upon the service. The years of life depend upon the average percentage of a complete cycle occurring between charging and the number of these occurring per year as well as upon other factors including the kind of duty in which the cell is operated and the care it receives.

ACCIDENTAL CONDITIONS. Accidental conditions arising from use or from the care given the battery are generally without injury to the nickel-iron-alkaline cell. Short circuiting, accidental charging in the reverse direction, accidental overcharging, or standing idle for an indefinite period in a discharged condition does not cause permanent injury. Vibration and jolting are not generally a cause of injury. Permanent injury will result from prolonged overheating above 115 deg fahr and prolonged operation with electrolyte level below plate tops.

MAINTENANCE. The principal points in caring for Edison alkaline batteries are as follows:

1. Maintain solution at the proper level with distilled water in each cell as recommended in the manufacturer's instruction booklet 850X (obtainable from Thomas A. Edison, Inc., West Orange, N. J.).
2. Avoid electrolyte temperatures exceeding 115 deg fahr.
3. Keep clean and dry the cells, trays, and the surface on which trays are placed.

DIRECT-CURRENT GENERATORS

1. APPLICATIONS

Direct-current, or, as it is sometimes called, continuous-current apparatus, was in very general use before the alternating-current type was introduced, and wherever the distance to which energy is to be transmitted is not a factor, there is no doubt that the d-c system is to be preferred. However, if energy is to be transmitted over long distances the a-c system with its transformer has unequivocal advantages. The result of these two conditions is that a compromise is adopted. The majority of the generating stations provide alternating currents and many of the motors use direct currents provided by rotary converters. Thus the d-c generators are becoming of less relative importance while the d-c motors maintain a very important position.

Any d-c generator may be used as a motor, and the principles of action and design are the same. The following paragraphs apply particularly to generators, and the special features of d-c motors are discussed under Direct-current Motors.

2. DEFINITIONS

The fundamental principle involved in the construction and operation of any type of dynamo-electric machine is the production of an electromotive force in one or more conductors by the relative motion of these conductors and a magnetic field. Such a machine may, as a rule, be used either as a generator or motor.

Shunt Machine. A shunt machine, either generator or motor, is one in which the entire field excitation is derived from a circuit of many turns and high resistance connected in "shunt" or multiple with the armature circuit. The characteristic of a shunt machine is poor regulation; that is, the voltage of a shunt generator decreases as the load increases. This is so marked that some shunt generators may be short-circuited, their terminal voltage dropping to zero, without resultant harm.

Series Machine. A series machine, generator or motor, is one in which the entire armature current flows through the field winding. Series generators are usually built to supply a constant current to an external circuit irrespective of the effective resistance of that circuit.

Separately Excited Machine. This type of machine is sometimes used in large stations where the exciting current is readily obtained from separately excited bus-bars and a voltage regulator is used.

Compound-wound Machine. This type of machine has on each field pole, in addition to its shunt winding, a few turns of thick wire which carry the load current and are known as the series winding. This winding causes the excitation to increase as the load increases and tends to keep the terminal voltage constant or even to increase it. If the field windings are proportioned to cause the voltage at full load to be higher than the voltage at no load the machine is said to be "over-compounded." A "flat-compounded" machine has the same voltage at full load and at no load; an "under-compounded" machine has a lower voltage at full load than at no load.

Short- and Long-shunt Connections. A compound-wound machine may be connected short shunt as in Fig. 1 or long shunt as in Fig. 2. The choice is merely a matter of convenience of station wiring.

Commutating Pole or Interpole Machines. These machines have small auxiliary poles alternately placed with respect to the main poles and excited by a few turns in series with the load. The effect of these poles is to improve the operation of the machine in the matter of commutation; see below.

Bipolar Machines. Small d-c machines are usually of the bipolar or two-pole type with a more or less inclosed frame of cylindrical shape.

Multipolar Machines. Large d-c machines are of the multipolar type, that is, have a large number of radial pole pieces.

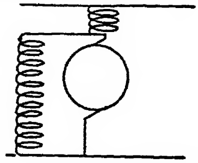

FIG. 1. Short-shunt Connection

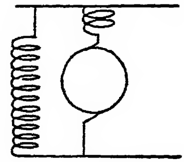

FIG. 2. Long-shunt Connection

Belt-driven and Direct-connected Types. Direct-current generators may be of either the "belt-driven" or the "direct-connected" type, as determined by the method of connecting to the driving unit. Belt-driven generators are characterised by a higher angular velocity than direct-connected.

3. RATINGS

The rating of a d-c machine is the output, together with such other characteristics as speed and voltage, assigned to it by the manufacturer. The continuous rating defines the load which can be carried for an unlimited period without causing any of the limitations, such as temperature, established by the Standardization Rules of the A.I.E.E., to be exceeded. See article on Standards.

VOLTAGE. The standard voltages for which d-c machines are built are:

80 volts for use on shipboard.

110–125 volts for lighting purposes and incidental small power motors, fan motors, and cooking utensils.

220 volts for three-wire systems with lighting and power combined.

500–600 volts for power alone and particularly for railway service.

1200–2400 volts for special railway service and heavy traction.

2000–6000 volts for series arc-light circuits fed by series machines.

SPEED. Machines are classified in commercial practice as high-speed, moderate-speed, and slow-speed. Table 1 shows roughly the suitable speeds and numbers of poles.

Table 1

Rating kw	High-speed		Moderate-speed		Slow-speed	
	Poles	rpm	Poles	rpm	Poles	rpm
0– 10	2	1500	4	1000	..	...
10– 50	4	1300	4	800	..	...
50–100	4	1100	4–6	700	6	300
100–300	6	850	6	500	8	200
300–500	6	750	8	400	10	150
500–up	6	650	8	300	12–up	100

4. PARTS OF A DIRECT-CURRENT MACHINE

The principal parts of a d-c machine are: the yoke, pole pieces, field coils, armature core, armature winding, commutator brushes, shaft, bearings, and mechanical frame or housing.

The yoke serves the double purpose of a mechanical support for the pole pieces or a framework for the whole machine and a path for the magnetic flux. It is always made of steel, sometimes of cast steel and more recently of forged steel bent to cylindrical form and welded to form a homogeneous magnetic ring.

The pole pieces, of forged or of assembled sheet steel, are usually bolted to the yoke and are formed with flaring projections at their inner ends to spread the flux over a considerable area of the armature and also to serve as a mechanical support to the field coils.

The pole pieces may be of solid steel or preferably built up of sheets of steel 0.025 in. thick and bolted together by insulated bolts passing through holes larger than the shanks of the bolts.

The pole pieces are usually wider at the face next to the air gap than in the main body in order to spread the flux over a greater area where it crosses the air gap to the armature. This enlarged section is called the pole shoe and may be integral with the

pole piece or a separate part bolted to it. The arc subtended by the pole shoe is usually from 60 to 70 per cent of the arc from the center of one pole to the center of the next pole.

The field coils consist of turns of copper wire wound upon a form which fits upon the pole piece. A current in these turns is the cause of the magnetomotive force which produces a flux in the magnetic circuit consisting of the yoke, pole pieces, and armature.

There may be two coils: a "shunt" of many turns of fine wire connected across the terminals of the machine and carrying current at all times; a "series" of a few turns of thicker wire connected in series with the armature and the load, and intended to strengthen the field as the load current increases.

The armature core is a hollow cylinder made up of many pieces of sheet steel, punched to shape and usually having slots punched around its outer periphery. The steel of the armature serves to carry the flux from one pole to the next, and the slots hold the various moving turns of wire known as the armature winding. The motion of this winding in the magnetic field is the cause of the generated emf, and a current in this winding is the cause of the force on the conductors which makes the armature move.

A general idea of the proportioning of the dimensions of an armature coil may be obtained from Table 2 showing usual practice.

Table 2

D = Arm. Diam., in.	Air Gap, in.	No. of Slots	Depth of Slots, in.	D = Arm. Diam., in.	Air Gap, in.	No. of Slots	Depth of Slots, in.
5	0.08	25– 40	0.6	30	0.15	80–150	1.50
10	0.10	30– 60	0.75	50	0.19	100–200	1.75
15	0.12	40– 80	1.00	100	0.25	150–300	2.50
20	0.125	60–100	1.25	150	0.35	200–400	3.25

The armature winding is an ingenious and special arrangement of the wires which gathers together in one path the conductors giving a voltage in the same direction, and thus multiplies the voltage of one conductor. There are many schemes of armature windings; those most common in d-c machines are described on pp. 8–05 to 8–08.

The commutator is peculiar to d-c machines. It causes a continual changing of the relative connection of the conductors inside the armature and the external circuit, so that, in spite of the fact that the voltage of each internal conductor is continually changing in value and direction, the external circuit receives a voltage of practically constant value and constant direction or polarity. The commutator consists of a large number of copper bars of a segmental cross-section, each insulated from its neighbors by mica and formed into a hollow cylinder.

The brushes are small slabs of carbon pressing and rubbing against the outer perimeter of the commutator, held in a definite place by "brush holders." Their function is to make a continuous electrical connection between the moving conductors of the armature and the stationary conductors of the external circuit, and to carry the current out from and back to the armature.

5. OUTPUT COEFFICIENT

The relation between the diameter and length of the armature and the output of any d-c generator (or the input of a d-c motor) are given by the following formula (see Principles Underlying Design of Electrical Machinery, by W. I. Slichter, Wiley):

$$D^2 L = \frac{610\, P\, 10^9}{\rho \sigma B N}$$

in which D = outside diameter of armature, inches.

L = length of armature, inches.

P = power output in kilowatts in case of generator.

P = power input in kilowatts in case of motor.

ρ = ratio $\dfrac{\text{pole arc}}{\text{pole pitch}}$, usually about 0.7.

Pole arc is the arc in inches covered by the pole face at the air gap.

Pole pitch is the arc from center to center of adjacent poles.

σ = ampere conductors per inch of armature periphery (see Table 3).

B = average flux density in the air-gap, lines per square inch.

N = revolution per minute at rating.

Ampere conductors per inch of periphery or specific loading, σ, is equal to the total conductors around the armature multiplied by the current in each conductor at rated load and divided by the perimeter of the armature.

The usual values for σ are given in Table 3.

Magnetic density in air gap, B, has values from 40,000 lines per square inch in small machines, 55,000 in medium, to 70,000 in large machines. Generally the density in the air gap is taken the same as the density at the pole face.

Table 3

Kw rating	For Continuous Rating	For Intermittent Rating
0–150	250–400	700
150–400	400–600	1000
400 and greater	600–900	1200

6. ELECTROMOTIVE FORCE INDUCED IN ARMATURE

Let Z = total number of armature conductors.
p = number of field poles.
m = number of parallel conducting paths between the positive and negative brush sets; that is Z/m is the number of armature conductors in series between positive and negative brush sets. (See below under Armature Windings.)
ϕ = total useful magnetic flux per pole.
N = revolutions of armature per minute.
f = frequency in cycles per second.

If a coil of wire be revolved about an axis in a magnetic field, as shown in Fig. 3, each length of conductor, or side of the coil, will pass entirely around the armature in $60/N$ seconds. The time taken for a conductor to pass through the magnetic field under each pole, or from a to b, is $\frac{60}{Np}$. Hence the average value of the emf induced in each armature conductor as it passes under each pole is $\frac{Np\phi}{60 \times 10^8}$ volts, since a cutting of 10^8 lines per second gives 1 volt. In an actual machine the conductors are uniformly distributed around the surface of the armature, therefore this is also the average voltage per conductor in each of the conductors between a and b at any instant. Since there are Z/m conductors in series between the positive and negative brush sets, the average value of the total emf between the brushes, when a suitable commutator (see below) is provided, is

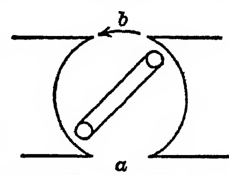

FIG. 3. Elementary Generator

$$E = \frac{p\phi ZN}{60 \times 10^8 m} \text{ volts}$$

The emf in each conductor alternates (i.e., passes through a complete cycle of positive and negative values) with a frequency of $f = pN/120$ cycles per second. Hence the formula for the average emf between brushes is

$$E = \frac{2f\phi Z}{10^8 m} \text{ volts}$$

The number of turns (S) in series between the positive and negative brushes is $Z/2m$, whence E may also be expressed as

$$E = 4f\phi S \times 10^{-8} \text{ volt}$$

7. ARMATURE WINDINGS

Though there is a large variety of types of armature windings, the practical man and even the designing engineer seldom meet types other than (1) the multiple-drum or lap winding and (2) the two-circuit series drum or wave winding. The other types may be used in a few special and exceptional machines, but a designer may work for many years without finding any necessity for using them.

MULTIPLE-DRUM OR LAP WINDING. This type of winding is very common in d-c machines, rotary converters, induction motors, and a-c generators. Its chief advantage is that it affords a very free choice in the number of coils and slots, and is very simple to lay out and connect. Its disadvantage is that it is not easily adapted to high voltages. Its chief characteristic is that there are always as many circuits in multiple and as many

studs of brushes as there are poles. The distinguishing feature in appearance is the direction of bending of the end connections, as represented by Fig. 4. The characteristic form of coils is shown in Fig. 7.

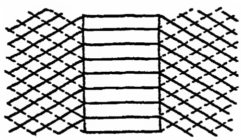

FIG. 4. Lap Winding

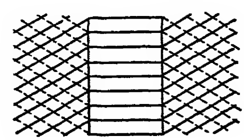

FIG. 5. Wave Winding

CONDITIONS FOR LAP WINDING. The customary simplex multiple-drum winding fulfills the condition expressed by the formula

$$C = pz = sb$$

where C = total number of coil-sides or bars.
p = number of poles.
z = average pitch * $= \dfrac{\text{front pitch} + \text{back pitch}}{2}$.
s = total number of slots.
b = number of coil-sides or bars per slot.

The total number of sides (C) is double the number of coils, as each coil has two sides. C must be a multiple of the number of slots (s) and of the number of poles (p).

The average pitch (z) must be an even number so that the front and back pitches may be different and odd $(z - 1)$ and $(z + 1)$, respectively. There are always two layers of coil-sides, top and bottom. One side of each coil lies in the top layer in one slot and in the bottom layer in another slot. The actual front and back pitches of a coil are always odd because they are made from a coil-side in the top layer (odd numbers) to one in the lower layer (even numbers) as in Fig. 6. Here the pitch is $14 - 1 = 13$.

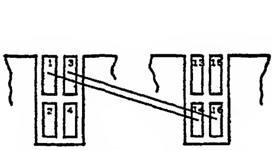

FIG. 6. Pitch of Connection

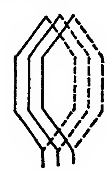

FIG. 7. Lap Winding

In order that the winding should progress continuously, the front pitch, or pitch of commutator connections, must differ by one coil (or two coil-sides) from the back pitch, or actual pitch of coils. The actual spread of a formed coil (Fig. 7) is the same front and back and is equal to the "back pitch."

The total number of coils, $Q = C/2$, is equal to the number of commutator segments and must be a multiple of the number of slots. In general if Q is a common multiple of the number of poles and the number of slots, a multiple-drum winding is possible. It is sometimes desirable that the number of slots should not be a multiple of the number of poles. In order to group the coils in poly-coils z should be a multiple of the coil-sides per slot.

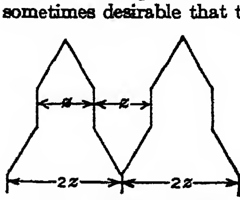

FIG. 8. Wave Winding

SERIES-DRUM OR WAVE WINDINGS, SIMPLEX. This type of winding is used in d-c armatures where the ordinary multiple drum would either give too low a voltage or require too many turns of fine wire in each coil. Its advantage is that it gives an armature that is better balanced magnetically and that only two brush studs are necessary. A greater number of studs may be used, however. There are always two circuits in multiple, regardless of the number of poles. The characteristic reverse bends of its face conductors are shown in Fig. 5. The characteristic form of the coils is represented in Fig. 8.

* Let the coil-sides be numbered consecutively from slot to slot, and let a point travel through the conductors in the order in which they are connected; if this point starting at conductor 1, say, passes through the point or commutator connection to conductor 8 and thus through the back connection to 3, then the front pitch is $8 - 1 = 7$ and the back pitch is $8 - 3 = 5$, and the average pitch is 6.

CONDITIONS FOR WAVE WINDING. The conditions to be fulfilled in laying out a series-drum winding are expressed in the formula

$$C = pz \pm 2 = sb$$

where C = total number of coil-sides or bars.
p = number of poles.
z = average pitch of end connections.
s = total number of slots.
b = number of coil-sides or bars per slot.

The total number of coil-sides (C) is double the number of coils and must also be a multiple of the number of slots. In the formula $+ 2$ is preferable to $- 2$, as the positive sign gives shorter end connections.

The average pitch z may be odd or even. If it is odd the front and back pitches are both equal to z. If it is even the front and back pitches must be $(z - 1)$ and $(z + 1)$. For a wire winding the back pitch must be one greater than a multiple of the coil-sides per slot b in order to fit the coils into the slots in groups.

The total number of slots (s) is very much restricted and is intimately connected with the number of poles unless the expedient of using a dead coil is used (see below).

The bars or coil-sides per slot b must be even and cannot be 4 or 8 in a 4-pole machine and cannot be 6 or 12 in a 6-pole machine, unless a dead coil is used.

USUAL ARRANGEMENTS for 4- and 6-pole machines with no dead coil are:

Four Poles. For $b = 6$, then z may be 25, 31, 37, etc., and usual values fulfilling all conditions are $s = 17, 21, 25$, etc. For $b = 10$, then z may be 47, 57, 67, etc., and s may be 19, 23, 27, 31, etc.

Six Poles. For $b = 4$, then z may be 17, 21, 25, etc., and s may be 26, 32, 38, etc.

USE OF DEAD COILS. By leaving one of the coils dead or out of circuit, a greater choice of slots and conductors is available. Four coil-sides per slot for 4 poles and 6 coil-sides for 6 poles may then be employed. In general $s \times b$ may be any number divisible by the number of poles. The formula is then

$$C = pz - 2 = sb - 2$$

Two bars or one coil are not connected in at all, and the number of commutator segments is equal to the number of active coils or one less than the total coils. The total number of active coils is $C/2$.

MULTIPLEX WAVE WINDINGS. It sometimes becomes desirable to provide a winding which has more than two circuits in multiple but not as many as the number of poles. In such a case a multiplex wave winding would be selected. These are windings in which the circuit passes completely around the armature more than once. If to do this we use two entirely separate electric circuits, we have a duplex doubly reëntrant winding, denoted by the symbol ○ ○. If, on the other hand, the winding closes on itself after passing twice around the armature, we have a duplex singly reëntrant winding, denoted by the symbol ◎. These types of windings are sometimes used when it is desired to have a number of circuits in parallel different from the number of poles. Thus we may have a 6-pole machine with 4 circuits in multiple which, with a given number of inductors, would give a greater voltage than a multiple-drum winding and lesser voltage than a series drum. This would be a duplex winding.

CONDITIONS FOR MULTIPLEX WINDING. The conditions are imposed by the formula

$$c = pz \pm 2\,m = sb$$

where the symbols have the same meaning as before and m is the number of multiple windings and $2\,m$ the number of circuits in multiple. If m and z are prime to each other we have a singly reëntrant winding. The greatest common factor of m and z gives the number of times the winding reënters, or in other words the number of independent windings.

The multiplicity and complexity may be carried to a very extreme limit. (See under Armature Windings in any standard textbook.) These multiplex windings are hardly ever used in the United States and England and only occasionally in Germany and France.

8. FLUX PER POLE

The value of the flux required to give the desired voltage is given by either of two formulas:

$$\Phi = \frac{E \times m \times 60 \times 10^8}{p\,Z\,(\text{rpm})} \qquad (a)$$

$$\Phi = \frac{E \times 10^8}{4\,f\,S} \qquad (b)$$

where Φ = flux lines per pole (useful).
E = the desired generated voltage.
m = number of parallel paths in the armature; see Armature Windings.
p = number of poles.
Z = total number of inductors on the armature.
rpm = revolutions per minute of the armature.
$f = \frac{p \times \text{rpm}}{2 \times 60}$ is the frequency induced in the armature.
$S = \frac{Z}{2m}$ = the turns of wire in series per path.

This flux flows from a north pole across the gap to the armature, divides so that one half goes to each of the adjacent south poles through the armature core then across the air gap, through a south pole, and from there through the yoke to the original north pole. Thus each pole piece carries two magnetic paths in parallel, while the armature core and field yoke carry one flux path.

In addition there is a leakage of flux from each pole piece, across the interpolar air space to the adjacent pole pieces. This flux never gets into the armature nor cuts the armature conductors. It is called the leakage flux (see explanation under A-c Generators). The ratio $\frac{\text{useful flux} + \text{leakage flux}}{\text{useful flux}}$ is called the leakage coefficient. It may be determined by the method given under A-c Generators or it may be assumed to have values as in Table 4.

Table 4

Rating in Kw	Leakage Coefficient
2.5	1.2–1.5
5	1.18–1.4
10	1.16–1.35
25	1.15–1.30
50	1.14–1.28
100	1.12–1.20
500	1.08–1.15

9. MAGNETIC CIRCUIT

It has been found advisable from experience to operate the various parts of the magnetic circuit (see Parts of a Machine) at certain conventional densities in order to keep the core loss and excitation within reasonable limits. The upper limits apply to a large or a slow-speed machine. Usual densities are given in Table 5.

Table 5

Part	Material	Lines per Sq In.
Field yoke	Steel	70,000–100,000
Field yoke	Cast iron	35,000– 70,000
Pole core	Steel	70,000–100,000
Air gap	Air	40,000– 70,000
Armature teeth	Steel laminations	90,000–125,000
Armature core	Steel laminations	60,000– 90,000

It is more convenient to analyse only one-half of the complete series circuit because the two halves are identical and the mmf for each half is supplied by each separate field coil. Thus, starting at a plane placed half-way between adjacent field poles, the main flux passes through the following parts in series: one-half the length in the yoke (i, Fig. 9), the pole piece (c), the air gap (g), the armature teeth (n), and one-half the length of the path in the armature core (k).

The number of ampere-turns required for excitation for any particular voltage or flux is calculated by means of a table as Table 6.

In the armature teeth and air gap, the total flux ϕ is equal to the useful flux per pole. In the armature core this flux is divided into two halves. The flux in the pole cores is greater than that in the air gap by the amount which leaks from pole tip to pole tip and from pole to pole.

By far the largest part of this leakage is between neighboring pole tips; thus it is reasonable to assume that the pole core carries the useful flux and the leakage flux, or the useful flux multiplied by the leakage coefficient.

Column 2 gives the total flux passing through each particular part.

Column 3 gives the cross-section of each part in square inches; the symbols refer to dimensions taken from a drawing similar to Fig. 9.

Column 4 calls attention to the fact that different materials have different permeabilities and magnetization curves.

Column 5 gives the density in lines or maxwells per square inch.

Column 6 contains the specific value of ampere-turns per inch for the particular material and density as taken from appropriate magnetization curves (see Sect. 2, §§ 15 and 16).

Table 6

1	2	3	4	5	6	7	8
Part	Flux	Cross-section	Material	Flux Density	Amp-turns per In.	Length of Path	No Load Amp-turns per Pole
Field yoke.....	$\nu\phi/2$	de	....	....	....	i	....
Pole core......	$\nu\phi$	$0.785\,f^2$ or fb	....	....	....	c	....
Air gap.......	ϕ	aLp	....	....	$0.313\,B$	Cg	....
Arm. teeth....	ϕ	$Tt_0\,l_i$	....	....	....	n	....
Arm. core...	$\phi/2$	hl_i	....	....	....	k	....

Net ampere-turns for flux: .....

Explanation of Table 6.

ϕ = useful flux per pole in maxwells.
ν = leakage coefficient.
a = pole arc in inches.
l_i = effective length of steel in armature core.
t_0 = effective width of tooth.
T = number of teeth carrying flux.
C = Carter coefficient.

Column 7 gives the length of the respective paths in inches, as taken from Fig. 9.

Column 8 gives the ampere-turns required for each part of the path, and is obtained by multiplying the respective values in column 6 by those in column 7. The sum of all values in column 8 is the excitation required in each field spool to establish the assumed value of useful flux. At no load this would correspond to a definite voltage as given by the formula in Art. 6.

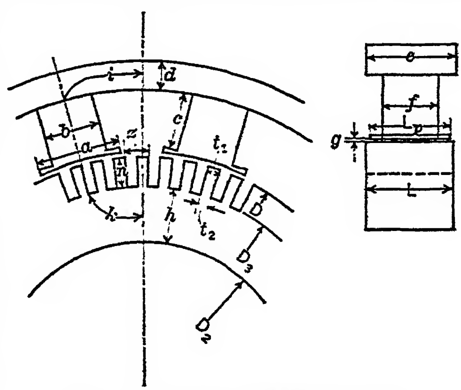

Fig. 9. Dimensions of Magnetic Circuit

Field poles are usually of laminated sheet steel, 25 mils thick, and the effective section of metal in them is usually 95 per cent of the actual cross-section, due to the insulating material between the steel sheets. The magnetic density in the pole shoe is usually so much lower than that in the pole core that it may be neglected. The purpose of a pole shoe is to make the area of the path of the flux across the air gap as large as possible and larger than the path in the pole core.

AIR GAP. The cross-section of the face of the pole shoe determines the cross-section of the path across the air gap. The pole shoe is usually rectangular in section, spans an arc of about 60 per cent of the pole pitch, but is about 0.5 in. less in length parallel to shaft than the armature core as the flux fans out at the ends. As a first approximation, the cross-section of the path of the flux in the air gap is taken the same as the area of the pole face.

If more accurate results are desired, it is necessary to consider the following effects:

(*a*) Fringing of flux at pole tips.
(*b*) Fringing of flux at the ends.
(*c*) Constriction of the flux due to air ducts in the armature.
(*d*) Constriction of the flux due to armature slots.

In many cases these four effects neutralize one another, (*c*) and (*d*) offsetting the favorable effect of (*a*) and (*b*). The effects (*a*) and (*b*) are simple to analyze, but (*c*) and (*d*) are more complex and are usually evaluated by means of the Carter coefficient.

The effect of the constriction of the flux in the air gap caused by the slots in the armature was analyzed mathematically by F. W. Carter in a paper in the *Transactions* of the Br.I.E.E. of 1901. The result is expressed in what is commonly known as the Carter coefficient, which is the ratio of the true reluctance across the gap with irregular distribution of flux to the simple geometrical reluctance (used in the text above). The Carter coefficient is a factor, greater than unity, by which the real length of the gap, g, may be

multiplied to get an effective length which may be used with the simple cross-section to get the correct value of the magnetomotive force required.

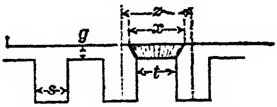

FIG. 10. Equivalent Length of Air Gap

In Fig. 10 let

g = actual or physical length of air gap.
g' = equivalent length of air gap.
l = length of iron core parallel to shaft.
s = width of slot at opening.
t = width of tooth face.
z = pitch of tooth and slot = $t + s$.
f = a numerical factor as in table.

The band of flux from any tooth spreads to a width greater than t and less than z. Let x represent this indefinite width; then let $x = t + fs$.

The apparent or simple reluctance of each band is $\frac{g}{l\,z}$, and the real reluctance is $\frac{g}{l\,x} = \frac{g}{l\,(t+fs)}$. The ratio of the real to the apparent is $\frac{z}{t+fs} = \frac{g'}{g} = C$, the Carter coefficient. The empirical constant, f, has been determined by Carter by mathematical analyses checked by tests and found to depend upon the ratio s/g, slot width divided by gap length, then

s/g	0	0.5	1	1.5	2	3	4	5	6	7	8	9	10
f	1	0.95	0.84	0.78	0.71	0.62	0.55	0.49	0.44	0.40	0.38	0.35	0.32

If the apparent density is obtained by means of the gross pole face area and the mmf found by means of the true gap, g, the correct mmf is found by multiplying this value by the Carter coefficient; or by multiplying the ampere-turns per inch for the apparent density by $g' = Cg$.

ARMATURE TEETH. At any given instant only a portion of the teeth carry flux. These are known as the "teeth under a pole" (T), and the number is slightly greater than those actually in the section subtended by the pole face, owing to the spreading at the pole tips. This spreading is such that the number of teeth under a pole is $T = \frac{a + 2g}{z}$. T may be a fractional number, as it is a time average.

The magnetic density in the teeth varies uniformly from a maximum at the root to a minimum at the face, and the mmf per unit length varies by a greater amount. Since the mmf required is the information desired it is usual to consider the "effective" section which gives average mmf. This is taken at a point one-third the distance from the narrowest end, thus the equivalent tooth section = $t_0 = \frac{t_1 + 2t_2}{3}$.

The effective length of iron (l_i) is the net length of magnetic material and excludes the space occupied by the ducts and by the insulation between laminations, thus = 0.9 (L-space of ducts). 0.9 is the stacking factor and applies to sheets having a thickness of 14 mils.

ARMATURE CORE. The length of the armature core between heads (L) is usually greater than the length of the pole piece by about 1/2 in. The core is made up of 14-mil steel, the same as the teeth, and the stacking factor is 0.9.

EXCITATION AT VARIOUS VOLTAGES, SATURATION CURVE. The relation between the actual voltage and the field mmf in ampere-turns or amperes for various voltages is plotted to give the "no-load saturation curve" and may be predetermined by repeating the foregoing calculation for different assumed voltages or may be determined by test (q.v.); see Fig. 25, p. 8–24.

10. SHUNT FIELD

The proper size of the wire in the shunt field coil is definitely set by three arbitrary quantities: the ampere-turns desired, the average length of a turn around the spool, and the voltage drop on the spool (see Slichter, Design of Electrical Machinery, Wiley).

Thus
$$q = \frac{\rho\, l\, F}{e}$$

where q = cross-section of proper size of conductor in circular mils.
ρ = 12.6 for copper at 75 deg cent—the resistance of 1 ft of copper wire of 1 cir mil area.
l = the average length of the turns on a shunt field in feet.
F = the ampere-turns per spool which are desired.
e = the voltage drop to be allowed on each spool for normal no-load conditions.

The proper number of turns, t, in the shunt field spool, is determined by the allowable current, or the allowable $I^2 R$ loss in the coil. This affects the efficiency of the machine and more particularly the heating of the coils. The greater the number of turns, the less will be the loss and the less will be the rise in temperature of the spools. Assigning a definite allowable value to this loss in watts or in field current, since watts per spool $= ei$, we have the fixed relation for the number of turns of the size of wire already chosen

$$t = \frac{eF}{\text{(watts)}}$$

The usual rise in temperature of shunt field coils of open d-c machines is about 60 to 80 deg cent per watt per square inch of outer cylindrical surface (omitting the end surfaces), and for a 40-deg rise on the spools, it is customary practice to allow from 0.5 to 0.6 watt per square inch of cylindrical surface.

In generators the allowable voltage per spool is taken 10 or 20 per cent below the rated voltage per spool to allow for a margin in emergencies.

An empirical method of determining the number of turns required is to set a density of 1000 amp per sq in. in the shunt field copper. This gives the current as $1000q = i_f$ and the number of turns as $F \div i_f = t$, where q is expressed in square inches.

11. ARMATURE RESISTANCE

By this is meant the resistance which the whole armature current meets in flowing from all the positive brushes to all the negative brushes, and is the resistance of two or more paths in parallel. In a series winding, there are only two paths in parallel. In a multiple winding, there are as many paths as there are poles. As all coils are alike and interchangeable, the average or mean length of a turn may be obtained from a drawing of one coil (see Fig. 11).

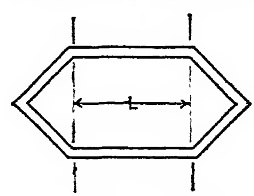

FIG. 11. Single Coil

The mean length of an armature turn is very closely approximated by assuming that the connections at each end have a length equal to a semicircle whose diameter is the winding pitch; thus, if the arc between the two sides of a coil is $\pi Dk/p$, where D = outside diameter of armature, k = the fractional pitch of the coils (if any) as a fraction, and p = number of poles, then the length of the end connections at one end is approximated very closely by $\pi^2 Dk/(2p)$, the length of the end connections at the two ends would be $\pi^2 Dk/p$, which may be written in round numbers $10Dk\ p$.

Then the whole length of a turn is m.l.t. $= 2L + 10Dk/p$ inches.

The resistance to the flow of the line current through all the parallel paths in the armature winding is

$$r_a = \frac{0.01\,N\,(\text{m.l.t.})}{12{,}000\,q\,m}$$

in which 0.0093 = resistance at 75 deg cent of a copper conductor 1000 ft long and 1 sq in. in cross-section.

N = number of turns in series in each path $= Z/(2\,m)$.

Z = total inductors on armature.

q = cross-section of conductor, square inches.

m = number of parallel paths.

If the cross-section of the conductor is circular and given in circular mils (cir mils) the resistance at 75 deg cent is

$$r_a = \frac{12.6\,N\,(\text{m.l.t.})}{12\,q\,m}$$

The voltage drop inside the armature is Ir_A, and the power lost in heat is $I^2 r_A$.

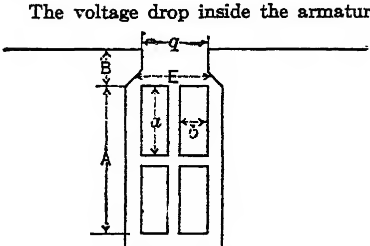

FIG. 12. Dimensions of Armature Coil

The rise in temperature of the winding T_W is given approximately by the relation (see Fig. 12)

$$T_W = \frac{100\,I^2 r_A}{(a+b)s(\text{m.l.t.})}$$

in which a = depth of one coil.

b = width of one coil.

s = total number of coils.

100 = rise per watt per square inch of coil surface with typical insulation used in low-voltage d-c machines.

12. DESIGN OF COMMUTATOR AND BRUSHES

The diameter of the commutator must be less than the diameter of the armature. The peripheral speed should be about 3000 ft per min and should not exceed 4000 unless a special construction is used. The number of segments should be such that the average volts per bar should be less than 15.

$$\text{Volts per bar} = \frac{(\text{Rated voltage}) \times (\text{Poles})}{\text{Number of segments}}$$

To avoid a weak construction the pitch of segments should not be less than 0.20 in. Of this amount about 30 mils is occupied by insulation.

DIMENSIONS OF BRUSHES. The width of the brushes is limited by the number of commutator segments which it is permissible to cover and the width of these segments. The number of segments covered is limited by the reactance voltage, as explained below. In general, the width of the brushes is from 2 to 3 times the pitch of segments. The area of the brush surface is such as to allow from 40 to 50 amp per sq in. of brush contact surface at full load. This surface is distributed equally over a number of studs equal to one-half the number of poles with a multiple-wound armature and may be all on one stud or disposed at pleasure with a series-wound armature.

TOTAL LENGTH OF COMMUTATOR. The total length of brushes per stud or the active length of the commutator is

$$l_c = \frac{2 \times (\text{Total surface of positive brushes})}{(\text{Width of brushes}) \times (\text{No. of studs})}$$

The total length of commutator is greater than this by about 0.5 in. to allow for clearances between brushes and at the ends. It is also customary to allow an extra space at the end of the commutator for insulation to prevent creepage. Commutators in general have a gross superficial area of 0.67 to 1.0 sq in. per amp of total current.

RESISTANCE OF BRUSHES AND BRUSH CONTACT. This is a complex and variable quantity partaking more of the character of the counter emf of an arc than a resistance. It is really a combination of a counter emf and a resistance in series. The magnitude of the loss is small compared with the other losses except in the case of low-voltage machines (80 volts or less) and it is therefore usually treated empirically and approximately.

The Standards of the A.I.E.E. state that a total drop of 2 volts in positive and negative brushes shall be assigned if pigtails are used and 3 volts if pigtails are not used. The total watts lost in all the brushes would therefore be the product of the total current by 2 or 3 volts, respectively.

Another method is to use the values for the resistance per square inch of each brush and brush contact as given in Table 7.

Table 7

Kind of Brush	Resistance of Each Brush, ohm				
	20 amp per sq in.	40 amp per sq in.	60 amp per sq in.	80 amp per sq in.	100 amp per sq in.
Hard	0.051	0.03	0.023	0.018	0.015
Medium	0.037	0.021	0.015	0.012	0.01
Soft	0.024	0.014	0.011	0.009	0.008

FRICTION OF BRUSHES ON COMMUTATOR. The value of this loss is

$$\text{Friction in watts} = \frac{(\text{No. of brushes}) \times (\text{Pressure per brush}) \times V_c \times k}{45},$$

where V_c = peripheral speed of commutator, feet per minute.
k = coefficient of friction = 0.25 for carbon and 0.14 for graphite.

The usual value of pressure on the brushes is from 1.5 to 2 lb per sq in. of contact surface.

RISE IN TEMPERATURE OF COMMUTATOR is

$$T = t \times \frac{(\text{Brush } I^2 r) + (\text{Brush friction})}{\text{Surface of commutator}}$$

where t has the value indicated in Table 8 and is the temperature rise in degrees centigrade for a total commutator loss of 1 watt per sq in.

Table 8

Peripheral Speed of Commutator, ft per min	Value of t
2000	15
3000	12
4000	10

13. ARMATURE REACTION (OR ARMATURE INTERFERENCE)

The armature reaction of a d-c machine has a very important influence on the commutation and regulation of both generators and motors. It is the effect of the mmf of the current in the armature conductors on the magnetic field set up by the field coils.

SEPARATE FLUXES BY FIELD AND ARMATURE CURRENTS. When current flows in the field coils and no current flows in the armature, a flux is set up following a path directly across the armature from pole to pole as in Fig. 13. On the other hand, when current flows in the armature and there is no current in the field a flux is set up in the armature across the axis of the poles, as in Fig. 14.

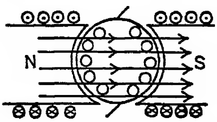

FIG. 13. Field Flux

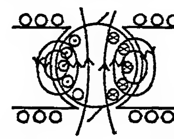

FIG. 14. Armature Flux

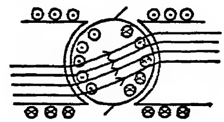

FIG. 15. Distorted Flux

RESULTANT FLUX. When both the field and the armature are excited, the flux is shifted around so that one tip of each field pole has its flux density increased and the other pole tip has its density decreased as in Fig. 15. If the brushes are at the geometrical neutral they are no longer on an axis at right angles to the flux; that is, they are no longer at the neutral point with respect to the resultant flux. With the brushes in this position the coil underneath a brush is cutting flux and generating a voltage, which is short-circuited by the brush and causes sparking. The brushes must, therefore, be moved a small angle in the direction of rotation in a generator (in the opposite direction in a motor) until they are on the neutral axis. The shift of the brushes aggravates the conditions, but nevertheless, unless the armature strength is too great, a position can be found in which a brush short-circuits a coil that is in the real neutral position and is inactive.

RELATIONS SHOWN VECTORIALLY. If certain approximations are made (see Sect. 3, Electrical Machines), the armature and field mmf's may be represented by vectors. In Fig. 16 F_1 and A_1 are the mmf's of the field and armature with the brushes on the geometrical or apparent neutral axis, and R_1 is the resultant of these. The brushes which are in line with A_1 are not at right angles to R_1. If the brushes are moved to an axis at right angles to R_1 as at A_2, then the resultant becomes R_2 and the desired conditions have not been attained. By moving the brushes still further to A_3, giving the resultant

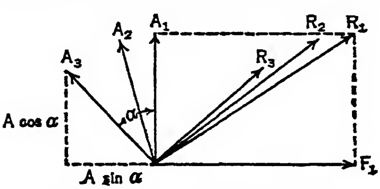

FIG. 16. Vector Relations of Mmf's

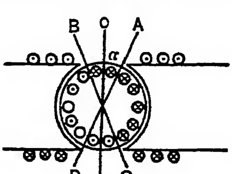

FIG. 17. Demagnetizing and Cross-magnetizing Turns

R_3, we are able to get R_3 and A_3 at right angles to each other. The stronger the armature flux as compared to the field flux the greater will be the angle through which the brushes must be moved.

When the brushes are moved through an angle α to the postion A_3 there is one component of the armature mmf, $A \sin \alpha$, directly opposed to the field mmf. Another component, $A \cos \alpha$, is at right angles to the field mmf. This is better understood by a reference to Fig. 17.

DEMAGNETIZING ACTION AND CROSS-MAGNETIZING ACTION. Let the movement of the brush from A_1 to A_3 be represented in Fig. 17 by the movement from O to B, or through the angle α. Then the conductors in the angle 2α, between A and B and between C and D, carry currents whose mmf directly opposes the magnetic strength of the field coils; these are known as back or demagnetizing conductors. The remainder of the armature conductors, in A–C and B–D, carry currents which give a mmf at right angles to the field and cause a distortion of the flux; these are known as cross-magnetizing conductors.

It should be noted that while all the conductors in the sections $A–B$ and $C–D$ subtending an angle $4\,\alpha$ constitute back ampere-turns, these are opposed to the strength of two poles. In the quantitative treatment in which the unit of design is a pole the turns of $2\,\alpha$ are used as the back ampere-turns per pole.

In practice the vectorial relations are not used because the space between the poles interposes a nullifying effect to the armature flux. In practice it is customary to call the effect of the conductors between A and B and between D and C the back-ampere turns and that of the conductors between B and V and between A and C the cross ampere-turns.

Quantitatively the armature reaction mmf per pole is the product of the turns in series per pole and the current in each conductor, thus:

Let Z be the total number of inductors on the armature; S the number of turns in series per path; I the total armature current; m the number of parallel paths; and p the number of poles. Then the armature reaction per pole is

$$AR = \frac{SI}{p} = \frac{ZI}{2\,mp}$$

If the brushes are on the geometrical neutral point all the armature reaction is cross-magnetizing. If the brushes are moved through an angle of α electrical degrees (one mechanical degree = $p/2$ electrical degrees as there are 360 electrical degrees for every pair of poles), then the back ampere turns per pole are $AR \times 4\alpha/360$ or $AR \times \alpha/90$. The number of cross ampere-turns is the difference between the total AR and the back ampere-turns.

For satisfactory performance there is an upper limit to the value of armature reaction per pole. Usual values are given in Table 9.

Table 9

Kw Rating	Armature Reactive Ampere-turns per Pole (AR)
0–100	1500–3500
100–300	3500–6000
300–500	6000–8000

The armature reaction ampere-turns per pole (AR) should not exceed certain values and should properly check those of Table 9.

If the (AR) comes out higher than advisable it is reduced by increasing the value of the flux.

EFFECT OF COMMUTATING POLES ON ARMATURE REACTION. The demagnetizing effect of armature reaction may be almost entirely overcome by placing the brushes in the neutral axis $O–O$ of Fig. 17. To prevent sparking under these conditions commutating poles must be used. The use of commutating poles does not in itself prevent armature reaction, but makes possible sparkless commutation when the brushes are set in such a position as to reduce armature demagnetization to a minimum.

STABILITY FACTOR. The stability factor is the ratio of the field ampere-turns for gap and teeth to the armature ampere-turns beneath the pole. The former are obtained from lines 3 and 4 of the tabulation for excitation and the latter are given by the formula

$$\frac{\text{Armature reaction ampere-turns per pole} \times \text{Pole arc}}{\text{Pole pitch}}$$

The field ampere-turns for gap and teeth must be greater than the armature ampere-turns, at the maximum current which will be used in the armature, by a ratio of 1.3 to 1.5 in a generator, and of 1.5 to 3 in a motor, if commutating poles are not used. If commutating poles are used this ratio is not important but is usually kept around unity.

The stability factor is adjusted to the value desired by using a greater length of air gap so that the field ampere-turns for gap are increased to the desired value.

EXCITATION UNDER LOADED CONDITIONS. When a generator carries a load, the armature reaction prevents the field coils from setting up as much flux as when there is no current in the armature. It is, therefore, necessary to have the field strength at any load greater than at no load by an amount sufficient to overcome or neutralize the armature reaction, or to provide special auxiliary poles for the purpose. There are three methods of estimating the effect of armature interference and overcoming it.

(*a*) It is common practice in the manufacture of d-c machines to provide a field coil of such ample capacity that it is sure to be more than sufficient to overcome armature interference and set up the flux desired. This field is then adjusted in practice by putting an adjustable resistance in series with the shunt field and a suitable resistance in multiple with the series field. For this practice it is usual to provide a total number of field ampere-turns per pole (F) equal to the net ampere-turns per pole at full load required for flux plus a number of field ampere-turns equal to 40 per cent of the armature reaction ampere-turns as calculated on the opposite page.

(*b*) The effect of armature reaction is divided into back ampere-turns and cross

ampere-turns. The excitation ampere-turns per pole to overcome the back ampere-turns (caused by shifting the brushes) is

$$A' = \frac{(\text{Armature reaction}) \times (\text{Brush shift in segments}) \times 2\,p}{\text{Total commutator segments}}$$

The excitation to overcome the effect of the cross ampere-turns depends upon many variables, but in machines designed in accordance with standard practice it bears a fairly uniform relation to the cross ampere-turns, depending upon the value of the ampere-turns in gap and teeth, as follows:

Cross ampere-turns = (Armature reaction ampere-turns) − (Back ampere-turns)

Field ampere-turns to compensate for cross ampere-turns is then $B' = K \times$ (Cross ampere-turns)

where K has values as shown in Fig. 18 (given by Cramp, see Bibliography). Thus the total field ampere-turns at full load is then equal to

$$F = (\text{Net ampere-turns for flux, Table 6}) + A' + B'$$

(c) It is possible by working with the saturation curve of the machine to actually determine the effect of the cross ampere-turns on the saturation in the teeth and pole face. This method is too elaborate and complicated to be discussed here and is of more value for educational than for practical purposes. It is discussed very fully in the books by S. P. Thompson and E. Arnold (see Bibliography, below).

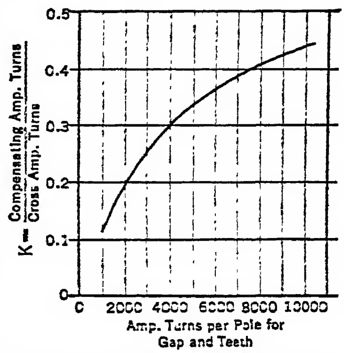

Fig. 18. Constant for Cross Ampere-turns

EXCITATION FOR VARIOUS LOADS. At no load the excitation required would be only that necessary to produce a flux corresponding to the rated terminal voltage. At any load corresponding to a current I the excitation in ampere-turns must be equal to the sum of: (1) that required to produce a flux corresponding to $E + r_a I$ at no load, where r_a is the total resistance of the armature between brushes, the brush resistance, and the resistance of the series field (see p. 8–09); (2) that required to overcome the back ampere-turns caused by I; and (3) that required to overcome the cross ampere-turns due to I.

SERIES FIELD. For a compound-wound machine the ampere-turns required in the series field are equal to the difference between the full-load ampere-turns and the no-load ampere-turns. As it is usual to shunt about 25 per cent of the current through a shunt resistance the number of series turns per pole for each coil is

$$t_1 = \frac{\text{Ampere-turns required}}{0.75 \times \text{Load current}}$$

The cross-section of each turn in square inches is taken equal to the full-load current divided by 1000.

This winding is usually wound in copper strap like a ribbon, the width being equal to the total length of field spool if it is wound under the shunt winding, or is arbitrarily chosen if the two coils are placed side by side. The thickness of each turn is the quotient of the cross-section divided by the width.

The coils are wound with an extra odd half turn to facilitate connection. Thus the depth of winding is

$$(\text{Thickness} + 0.016 \text{ for insulation})\ (t_1 + 1)$$

Allowance for a layer of insulation inside and outside adds about 0.375 in. to the depth of winding.

The mean length of turn l_f' is (see Fig. 9):

For square pole l_f' = (periphery of pole) + 4 (depth of winding), inches.
For round pole $l_f' = \pi\,(f +$ depth of winding).

The resistance per spool is

$$r_1 = \frac{0.0093\, t_1\, l_f'}{12{,}000\, q_1}$$

where q_1 is the cross-section of a turn in square inches.

The total drop in voltage in the series field is $0.75\, r_1 I$, which should be between 0.5 and 1 per cent of the rated voltage.

14. COMMUTATION

ARMATURE INDUCTANCE. Each coil of the armature carries a current flowing in one direction as it travels from a positive brush to a negative brush and in the opposite direction as the coil travels from a negative to a positive brush. Thus the direction of the current in each coil reverses during the time the commutator bars to which the coil is connected pass under the brush. To reverse the current in any circuit it is necessary to take out the energy stored up in the form of magnetic flux linked with the circuit, and put back an equal amount represented by a flux in the opposite direction. In doing this there is induced in the circuit a voltage which is proportional to the time rate of change of the flux and which opposes any change in the value of the current. This voltage is the emf of self-inductance of the coil.

METHODS OF IMPROVING COMMUTATION. To minimize the voltage of self-inductance it is necessary to keep the number of ampere-turns in each coil as low as possible and to cause the reversal to take place as slowly as possible. It is possible to neutralize the voltage of self-inductance by introducing an opposing voltage, which is accomplished in practical machines by giving the brushes a forward lead or by using interpoles.

FORWARD LEAD OF BRUSHES. The brushes are moved in the direction of rotation in a generator (opposite direction in a motor) away from the true neutral until the coil undergoing reversal is moving in a flux coming from an adjacent pole tip of such a density that it induces by rotation in that particular coil a voltage that opposes and neutralizes the voltage of self-inductance.

EFFECT OF COMMUTATING POLES ON COMMUTATION. Interpoles or commutating poles are placed between the main poles over the neutral space. These poles are excited by the load current until they give a flux of the proper direction and value to induce the desired neutralizing voltage. (See also above under Armature Reaction.)

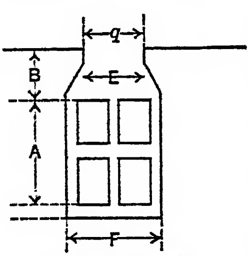

FIG. 19. Slot Diagram

INCREASING RESISTANCE IN PATH OF SHORT-CIRCUIT CURRENT also aids commutation. This changes the time constant of this circuit; that is, some of the stored energy of the magnetism is dissipated in I^2R loss in this resistance instead of in parking at the brush. The usual method of accomplishing this is to use carbon brushes which have a higher resistance of contact than metal brushes. Another method is to introduce a high resistance in the connection between the winding and the commutator segment.

REACTANCE VOLTAGE. The armature leakage flux per ampere-conductor may be resolved into three parts for convenience in analysis. These three fluxes are: P_s flux inside the slot itself, P_t flux from tooth tip to tooth tip, and P_c flux about the end connections.

Referring to the dimensions in Fig. 19 these fluxes are given by the expressions:

$$P_s = 3.2\,l\left(\frac{A}{3F} + \frac{B}{E}\right)$$

$$P_t = 2.35\,l \log_{10}\left(\frac{\pi m}{2q}\right)$$

$$P_c = 0.58\,l_c\left(\log_{10}\frac{2\,lc}{U c}\right)$$

where l = length of iron core.
m = interpolar distance between pole tips, Fig. 19.
q = width of slot opening at face.
l_c = length of end connection at one end.
U_c = perimeter of one coil of end connections.

All dimensions are in inches.

Also let t = turns in series between adjacent commutator segments
= turns per coil in a multiple winding
= $p/2$ times turns per coil in a series winding.

$$C = kt\frac{\text{(brush thickness)}}{\text{(segment pitch)}}.$$

k = 2 for a full pitch winding and approaches unity as the pitch decreases.

Then
$$L = 2\,Ct\,(P_s + P_t + Pc)10^{-8}\text{ henry}$$

Frequency of commutation,

$$f_c = \frac{12\,V_c}{120\text{ (brush thickness)}}$$

V_c = peripheral speed of commutator, feet per minute

$$I_c = \text{amperes per circuit in armature} = \frac{(I\text{ line})}{\text{no. of mult. cir.}}$$

Then assuming that the current in the short-circuited coil varies according to the sine law, the maximum value of the reactance voltage is

$$e_x = 2\pi f_c L I_c \text{ volts}$$

COMMUTATING POLES are used where either the armature reaction or the reactance voltage is very great. If the armature reaction at full load is greater than 80 per cent of the field ampere-turns at no load, then interpoles should be considered. If the reactance voltage is greater than 2.5 volts, interpoles should be considered.

The design of the interpoles may be made roughly in accordance with the practice in some of the large companies by making their widths equal to the widths of two slots and two teeth, and proportioning the winding to have 1.4 times as many ampere-turns as the armature reaction ampere-turns (AR). The axial length of the pole is frequently less than that of the armature; the gap density should be about 30,000, and the iron or steel of the pole should not be saturated when 1.5 times the full-load current is flowing through its windings.

In practice a shunt having inductance is connected across the terminals of the interpole winding and adjusted for sparkless commutation. When the interpoles are used on a compound-wound generator, it is possible to decrease the strength of the series coils to such a value as will produce the proper flux for the desired $E + r_a I$, letting the interpoles take care of the armature reaction. Series coils having 20 per cent as many ampere-turns as the armature will be satisfactory.

EXACT DESIGN OF COMMUTATING POLES. A more exact method starts with the value of the reactance voltage, e, and an assumed density in the air gap of B_1 = 30,000. The axial length of the interpole is then

$$L_1 = \frac{10^8 \times e}{k B_1 v_a}$$

where v_a = the peripheral velocity of armature in inches per second, and k = number of inductors in series in short-circuited coil = $2t$ (see formula for reactance voltage, above).

The width (a_1) of pole at face is made equal to or a little greater than twice the pitch of armature slots. The flux per pole in gap is $\phi_1 = B_1 L_1 a_1$.

The leakage coefficient is higher for interpoles than for the main poles and is in the neighborhood of 1.6 to 1.8.

The magnetic density is kept low in the pole core so that there will be margin for overload.

The necessary exciting ampere-turns to force this flux through the gap and to take care of the leakage and increased densities in the field and armature core are calculated. Let this value be A''.

Let the armature reaction ampere-turns per pole be B''.

Then the total ampere-turns on the interpoles should be $A'' + B''$.

The number of turns per pole is $(A'' + B'')$ divided by the full-load current of the machine, and the winding itself is laid out in the manner employed in laying out the series field.

15. REGULATION

This is arbitrarily defined as the ratio $\frac{E_0 - E}{E}$, where E_0 is the voltage at the terminals of the machine with no load connected, E is the voltage at the terminals when a load is connected, and the ratio is the regulation for that particular load. It is usually expressed as a percentage. The test is made by connecting a specified load to the generator, adjusting the excitation to get a specified voltage (with rising field current) and then opening the connection to the load without making any change in the shunt field rheostat, but usually holding the speed constant. Where generators are sold direct-connected to their own prime movers the speed is allowed to change in accordance with the governing of the prime mover. This is then the regulation of the set.

With shunt machines the voltage at full load is always less than at no load and the regulation is said to be a positive number. With compound-wound generators there may be over-compounding; that is, the voltage at full load is greater than that at no load and

the algebraic sign of the regulation would be negative. The regulation of a compound generator is determined with a falling field current; that is, the voltage is first raised to a value higher than normal and then brought down to the specified value before recording readings. This is because a compound generator frequently shows higher values of voltage at fractional loads than at no load, owing to the hysteresis loop.

16. LOSSES

CORE LOSS. The core loss consists of hysteresis and eddy-current losses in the armature core and teeth due to the reversal of the useful or main flux as the armature passes each pole. It is most readily calculated by using the values (C_h) of the hysteresis loss per cubic inch at one cycle per second for the specific magnetic density and (C_e) the eddy-current loss per cubic inch at one cycle per second for the specific density and thickness of sheet (usually 0.014 in., standard). These values are given for various qualities of steel (η and ϵ) in the curves in the article, Magnetic Materials (see Sect. 2, § 16).

$$\text{Total loss in core} = V_c\, C_h\, f + V_c\, C_e\, f^2$$

$$\text{Total loss in teeth} = V_t\, C_h\, f + V_t\, C_e f^2$$

where V_c and V_t = volume in cubic inches of the core and teeth respectively and f = frequency = poles × rpm/120.

C_h and C_e (see above) are taken for those densities which exist when the flux corresponding to the generated voltage at a specific load is maintained, i.e., $E + I\, r_a$ in a generator and $E - I\, r_a$ in a motor, where E is the terminal voltage and r_a the resistance of the whole armature circuit.

The prediction of the core loss from the design is one of the most unreliable calculations because the pulsation of the flux due to the passage of the teeth across the pole face introduces extra losses which are very difficult to predict except by very elaborate and complicated methods (see Bibliography). For convenience the value calculated as above is sometimes multiplied by an empirical factor of 1.2 to 1.5 to cover these extra losses.

FRICTION AND WINDAGE can be calculated by formula for any particular line of similar machines, but no method applicable in general can be given. Machines are designed so that the value of the friction loss very closely approximates those given in the table on the opposite page. The true friction varies directly as the speed, and the windage as the square of the speed. In shunt machines the speed does not change much with the load so this loss may be assumed constant in this class of machines (see Direct-current Motors).

BRUSH FRICTION LOSS. See p. 8–12.

STRAY POWER LOSS. This term is sometimes used to include both the core loss and friction and windage.

EXCITATION LOSS OR RI^2 IN SHUNT FIELD. Since in a self-excited machine the loss in the field rheostat is charged against the machine the total loss is equal to the terminal voltage multiplied by the current in the shunt field. The loss is usually constant and subject only to the arbitrary variations due to hand regulation.

RI^2 LOSS IN ARMATURE CIRCUIT, including the brushes, series field and connections, varies as the square of the armature current, and, therefore, approximately as the square of the load, and also irregularly to a small extent due to the variation of brush contact resistance with the value of the current. The temperature of the copper must also be considered, usually assumed as 75 deg cent. (See Resistance and Conductance.)

LOAD LOSSES, STRAY LOAD LOSSES. The mmf of the armature sets up a component of flux of its own whose magnitude is closely proportional to the armature current (because its path is purposely largely in air) which distorts the main flux and causes additional losses under load. These are: eddy currents in the armature conductors and in any masses of metal near the conductors, such as the pole faces, and increased hysteresis in the teeth and pole faces. This loss is zero with no armature current and increases rapidly with the armature current. Its rate of increase depends upon how much of it is hysteresis and how much is eddy loss.

The A.I.E.E. Standards say that for calculating the efficiencies of direct current generators or motors the load losses at any load shall be taken as 1 per cent of that output except for motors of 200 hp at 575 rpm and smaller, in which cases they shall be ignored. Some European standards say the load losses shall be taken as proportional to the square of the load. There is no recognized method of calculating or testing for them.

EFFICIENCY. The efficiency is the ratio of the output to the sum of the output and all losses. It is predetermined by estimating the value of each of the five losses described above for the particular load or output under consideration.

If P = the output in watts and the symbols A, B, C, D, and E represent respectively the various losses described above, then the efficiency for any load, P, is:

$$\text{Per cent efficiency} = \frac{100\,P}{P + A + B + C + D + E}$$

The efficiency is a maximum for that load at which the variable losses ($D + E$) are equal to the constant losses ($A + B + C$)—hence the desirability of keeping the constant losses small in a machine which is to be operated most of the time at partial load.

USUAL EFFICIENCIES AND LOSSES. An idea of a reasonable value for the efficiency of d-c machines of various sizes and the distribution of the losses is given in the following table. It must be remembered that the efficiency of a machine of any given size may vary throughout a wide range depending upon the speed, weight, and cost.

Rating, kw	Efficiency, per cent	Friction (total), per cent	Excitation, per cent	Core Loss, per cent	Arm. RI^2, per cent
1	80	6	6	4	4
5	84	5	4.2	3.2	3.6
10	86	4	3.6	3.0	3.4
20	88	3	3.0	2.8	3.2
50	90	2.6	2.2	2.2	3.0
100	91.4	2.3	2.0	1.7	2.6
200	92	2.2	1.8	1.6	2.4
500	93	2	1.6	1.4	2.0

17. HEATING

The rise in temperature of the field coils is discussed above under that heading, and a rough criterion for the heating of the armature coils is given under Armature Resistance.

It is desirable to determine more accurately the rise in temperature of the armature conductors, as the insulation on the windings will be injured if this temperature is excessive.

The temperature of the windings is affected not only by the heat due to $r_a I^2$ in the copper, but also by the heat from the core loss in the iron, and both losses must be taken into consideration in order to make an accurate prediction of the final temperature of the copper.

The following rational method takes into account the most important factors and, with a judicious choice of constants, gives reliable results. However, the drop in temperature due to conduction of heat inside the copper conductors and inside the iron core is neglected in the interest of simplicity and because it is small and of negligible effect except in very long machines such as turbo-generators.

All the heat loss in the armature is dissipated either at the surface of the iron (including that in ventilating ducts) or at the surface of the "end connections," sometimes called the "free ends" of the winding coils, as distinguished from the "imbedded portions." If the copper loss is great the copper will be hotter than the iron and some of the $r_a I^2$ will flow from the copper through the insulation in the slots to the iron and thence to the surface of the core iron. However, if the core loss is excessive or great compared with the copper loss the temperature of the iron will be higher than that of the copper and the direction of flow of heat energy will be reversed, some of the core loss passing from iron to copper and to the end connections which are cooled by air, either circulated by the rotation of the armature or by a system of forced ventilation or blowing.

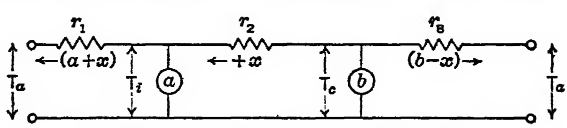

Fig. 20. Equivalent Circuit for Heat Losses

Thus there are two sources of heat, the core loss in the iron and the $r_a I^2$ in the copper, and two paths for the flow of the heat energy to the ventilating air, these paths being linked together by a third path between the copper and the iron. This may be represented by an electrical network as in Fig. 20.

Let a = core loss in watts.

b = armature copper loss in watts.

x = watts passing copper to iron, or vice versa.
r_1 = resistance of heat path from iron to ventilating air at surface of iron core and ducts.
r_2 = resistance of heat path from copper to iron through the insulation in the slots.
r_3 = resistance of heat path from copper to air through the insulation on the end connections. (This includes both the drop due to conduction through the insulation and due to convection at the surface.)

Then:
$$r_1 = t/A$$
$$t = \frac{170}{1 + 0.00025\, V}$$

V = peripheral velocity of the armature, feet per minute.
$$A = \pi DL + \pi/4\,(D^2 - D_2^2)\,(2 + 2d)$$

D = outside diameter of armature, inches.
D_2 = inside diameter of armature.
L = length of armature, inches.
d = number of air ducts in the armature core.
$$r_2 = \frac{k_1\, d_1}{U_s\, L\, s}$$

k_1 = specific heat resistance of the insulating material, 160 to 250. (See note.)
d_1 = thickness of insulation, in inches, between copper in the slot and iron of the core.
U_s = perimeter of slot insulation including two or more coils.
s = total number of slots.
$$r_3 = \frac{k_1\, d_2 + t}{U_c\, l_c\, Z}$$

d_2 = thickness of insulation on end connections.
U_c = perimeter of one coil at free part of end connections.
l_c = length of end connections or free part of a coil at one end of the armature.
Z = total number of coil sides = twice the number of coils.

Then by Kirchhoff's laws as shown by the circuit diagram of Fig. 20 there are two simultaneous equations:

Rise in temperature of the copper
$$T_c - T_a = (a + x)r_1 + xr_2$$
$$T_c - T_a = (b - x)r_3$$
where T_c is the actual temperature of the copper as measured by resistance and T_a is the temperature of the ventilating air.

From these equations:
$$x = \frac{br_3 - ar_1}{r_1 + r_2 + r_3}$$

The rise in temperature at the surface of the iron of the core will be:
$$T_i - T_a = (a + x)r_1$$

EXPLANATION OF THE CONSTANTS. t is the drop in temperature in degrees centigrade between the surface of the armature and the surrounding air ("ambient") for one watt per square inch. The value 170 is an empirical value to be used when the actual velocity of the air is not known but only the peripheral speed of the surface of the revolving part. If the true velocity of the air with respect to the surface, V, is known then the relation is:
$$t = \frac{130}{1 + 0.0005\, V}$$
(See Langmuir, A.I.E.E.)

k_1 is the drop in temperature per watt per square inch due to conduction through insulation having a thickness of one inch. For any other thickness, d_1 (inches) the drop is $k_1\, d_1$. k_1 is from 160 to 200 deg cent for varnished-cambric insulation and 250 for built-up mica insulation. The value is much affected by the treatment to exclude air pockets, and the lower values of the constant apply to insulation very carefully built up and heat treated.

d_2 is the thickness (inches) of the insulation on the end connections or free parts of the coils which is usually less than d_1 in the imbedded portion because of the "slot insulation" around that portion.

Usually four or six coil-sides are bound together in the slot to make a polycoil but are separated at the free ends, hence the reason for distinguishing between the number of slots and the number of coil-sides in the formulas for r_2 and r_3.

18. SPECIAL MACHINES

SERIES ARC-LIGHT GENERATORS. These machines are intended to give a constant value of current in the external circuit irrespective of the resistance or counter emf in that circuit. This is accomplished by causing the voltage impressed on the external circuit to decrease whenever there is tendency for the current to increase. The load usually consists of a number (20 to 50) of arc lamps connected in series, each taking about 40 volts. Each lamp requires the same value of current, and the total voltage is proportional to the number of lamps in use. If a lamp is no longer needed it is short-circuited by a switch and the current in the remainder of the lamps remains the same because the generator automatically reduces the voltage supplied. This regulation of the current is obtained by two or more of the following means: (1) high armature reaction which tends to weaken the field whenever the current increases; (2) movable brushes to vary the number of turns in series between brushes; (3) a series field arranged so that turns may be shunted, short-circuited, or cut out; and (4) a high degree of saturation in the magnetic circuit of the field so that the flux changes very slightly for considerable change of mmf.

The pole face density is usually quite high and the path of the flux in the field is of high reluctance, whereas the path of the armature flux is of low reluctance; thus there is much field distortion. The machines are usually wound for 2000 to 4000 volts. The distorting effect of armature reaction is usually relied upon to take care of sudden and small variations of the load, and large and lasting variations of the load are taken care of either by moving the brushes to another position giving either a lower or higher voltage, or by commutating or shunting some of the turns of the series field.

Brush Arc Machine. This was the first arc-light machine to be brought out. It consists of a ring armature having a winding of the open-circuit type. There are a number of spool-wound coils on the armature, diametrically opposite coils being connected in series to an independent pair of commutator segments. The brushes make a series connection of the various groups of coils, the coils of highest emf being connected in series, those of medium emf in multiple, and those of low emf being left out of circuit. The numerous field poles are on both sides of the ring armature. The two poles facing each other are of the same polarity so that the flux flows along the ring of the armature from one pole to the next pole on the same side of the ring. Regulation is obtained by shunting field turns and shifting the brushes for good commutation. A rotary oil pump is used as a regulator to move the handle of the field regulator and to move the brushes.

Thomson-Houston Arc Dynamo. This machine contains a spherical-shaped armature with a three-part open-circuit winding, the three windings being spaced at 120 deg on a ring armature and connected in "Y," the terminals going to the segments of a three-part commutator. The commutator has air spaces between segments and a jet of air to blow out any arcs between brushes and segments. There are four brushes on the commutator, connected in pairs. At some part of each revolution two coils are in multiple, at other positions only one. A relay moves the brushes so that as the load increases the positive and negative brushes move farther apart, thus giving more voltage. As one brush of a pair moves forward the other moves backward, thus keeping them symmetrical with respect to the neutral axis. The field structure is of a hollow, cage-like construction.

Wood Arc-light Machine. This generator has a closed-circuit Gramme ring armature with a commutator having a large number of segments. Regulation is obtained by moving the brushes so as to vary the voltage available and by the use of a high armature reaction balancing the field mmf.

HOMO-POLAR GENERATORS. This type of machine is also sometimes called "acyclic" and was formerly incorrectly called unipolar. Its method of operation is based on the principle of the Faraday disk, which consisted of a copper disk revolving about an axis and projecting between the poles of a magnet. By this rotation in a magnetic field an emf is set up between the axis and the periphery of the disk, and if brushes bearing on these two parts are connected to an external circuit a current will flow. The peculiar characteristic of a homo-polar machine is that each conductor always cuts the flux in the same direction, consequently the emf induced in it is always in the same direction and is not alternating as in the usual d-c machine. Thus no commutator is required.

This absence of a commutator is the feature which makes the homo-polar machine attractive. The commutator presents many difficulties in high-speed machines to be driven by steam turbines. It is for this application that recent attempts to develop a successful homo-polar machine have been directed. Instead of a commutator, collector rings with brushes are used to collect the current from the moving conductors. These collector rings, however, present difficulties in construction and operation on account of

the high peripheral speed at which they must run. The rings are subject to a considerable centrifugal force, and there is a tendency of the current to arc between the brush and the collector on account of the high rubbing speed.

Voltage. The voltage of such a machine is not only unidirectional as in all d-c machines but is really constant. But since there can be only a few conductors in series, the voltage generated is very low. The voltage generated per disk or inductor is

$$E = Blv\,10^{-8}$$

where B = magnetic lines per square centimeter, l = length of conductor in centimeters, v = velocity of conductor in centimeters per second.

This is more conveniently expressed,

$$E = \frac{NZ\phi\,10^{-8}}{60} \text{ volts}$$

where N = revolutions per minute, Z = conductors in series, ϕ = total flux traversing gap.

Radial and Axial Types. There are two types of homo-polar machines, the radial and the axial. The radial type (Fig. 21) is like the Faraday disk and consists of a disk revolving between the two poles of a cylindrical magnet. Brushes bear on the outer rim and the shaft to collect the current. The disk may be made of steel to reduce the reluctance of the magnetic path. The voltage of such a machine is limited to 10 or 15 volts, but the current may be very large. A variation of this type has two disks on the same shaft and the magnetic path so arranged that the voltage of the two disks may be added in series by brushes bearing on the peripheries of the two disks. The axial type (Fig. 22) consists of a cylindrical steel armature with copper bars in the surface, the whole revolving in a cylindrical field so arranged that the magnetic flux flows outward from the armature in a radial direction at all points. The several conductors on the armature are connected to slip-rings at both ends, and by means of brushes and stationary conductors, these conductors are connected in series. The voltage of such a machine may be from 40 to 50 volts per conductor.

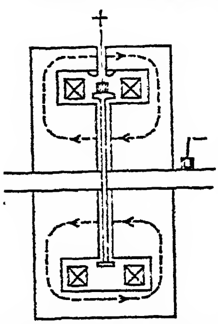

Fig. 21. Radial Type of Homo-polar Generator

Data on Large Axial Type Machine. In the *Trans. A.I.E.E.*, Vol. 24, Noeggerath describes a machine of the axial type rated at 300 kw for 500 volts at 3000 rpm. The armature has 12 conductors connected in series for 500 volts. The diameter of the armature is 19 in. and the length 12 in. The peripheral velocity is 15,000 ft per min. The armature is of cast steel and has 24 cast-steel collector-rings on it. The stationary conductors connecting the collector-rings together are placed in the face of the pole, and thus their mmf may be used to balance the armature reaction.

Excitation. The armature reaction of such machines is very high and has only a distorting effect. However, it weakens the field as the cross magnetization weakens one part more than it strengthens another due to saturation. By a proper arrangement of the movable connections between the collector-rings and stationary conductors a mmf may be set up which will strengthen the field and thus the machine may be compounded. These machines may be made self-exciting, but the resistance of the shunt fields must be very low in order that the machine may pick up on starting as the resistance in the brush contacts is high. The drop in voltage in each brush contact is about 0.8 volt at full load but is higher before the current flows. It sometimes requires from 10 to 20 times the normal voltage of brush contact to start the current.

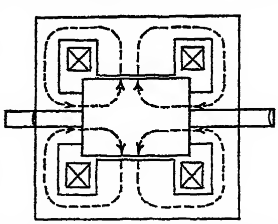

Fig. 22. Axial Type of Homo-polar Generator

Losses. Such a machine as described above has an efficiency of approximately 90 per cent at full load. The losses are made up principally of friction and $I^2 r_a$ in the brushes. The field $I^2 r_a$ is low as the air gap is small for mechanical considerations. The armature $I^2 r_a$ is almost negligible owing to the few turns. The eddy losses are low if the flux density is constant in one zone around the armature but the density may vary along an element of the cylinder. The total weight of the machine is about the same as that of the usual d-c machine but the proportion of copper is much lower.

THREE-WIRE DIRECT-CURRENT GENERATORS. The three-wire generators, used for supplying a three-wire d-c system and taking care of a reasonable unbalance of

the loads on the two legs, is really a double-current generator with collector rings as well as a commutator. It may have two, three, or four rings. The more phases, the less is the internal heating caused by the unbalanced current. The neutral of the distribution system is connected to the neutral or middle point of each of the "balance coils" or single-circuit transformers and the terminals of these coils are connected to the collector rings.

For a two- or four-ring connection the coils must have a tap at their middle point, but for a three-ring machine a Y connection may be used.

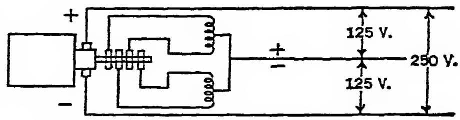

FIG. 23. Three-wire Direct-current Generator with Four Collector Rings and Two Coils

The unbalanced or neutral current divides among the coils inversely as the resistances, therefore equally. When the current enters the armature winding from the ring it divides again inversely proportionally to the resistance of the path to the brush whence the unbalanced component came originally. Thus the unbalanced current in any one coil of the armature is continually changing and reverses as the coil passes under a brush. The variation is a straight-line function, and this component is superimposed on the current in the armature due to the balanced portion of the load. A coil half-way between taps has a lower peak of varying current than a coil next to a tap as in a synchronous converter and hence less heating.

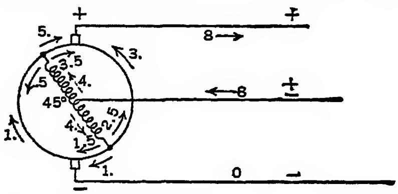

FIG. 24. Three-wire Generator. Path of Unbalanced Currents in a Two-ring Machine

Inside figures show the mathematical components of each 4 amp from coil terminal.
Outside figures show the actual currents in the armature coils at that instant.

An a-c magnetizing current of small magnitude is continually flowing from the collector rings through the coils whether the load is balanced or not. In some commercial machines the coils are placed inside the rotating armature, in which case only one collector ring is needed; but generally the coils are separate and external to the generator and encased in a structure like a transformer.

19. TESTING OF DIRECT-CURRENT MACHINES

Direct-current machines are judged by four characteristics: efficiency, regulation, commutation, and heating. It is necessary to subject a machine to actual full-load conditions to determine its heating and commutation, and it is desirable to do so to determine the regulation, but the efficiency is determined more accurately by the "separate loss method" which does not involve loading the machine.

The customary tests on d-c machines are (see also A.I.E.E. Test Code):

(1) Resistance measurements, cold and hot. (2) Saturation curve. (3) Core loss and friction test. (4) Load run for commutation and regulation. (5) Heat runs. (6) Compounding test. (7) Insulation test.

RESISTANCE MEASUREMENTS. The first measurements are made when the machine is at the same temperature as the room, that is, after it has been idle from 12 to 24 hours depending upon its size. This is in order that the relation between the resistance and temperature may be accurately known. The resistance of the shunt-field, series-field, and armature winding proper is measured.

RESISTANCE OF LAP WINDING. In measuring the resistance of the armature winding it is preferable to measure between two diametrically opposite points of the commutator of a multiple-wound armature. The effective resistance of the armature is calculated from this by the formula

$$r_a = \frac{4r'}{p^2}$$

where r' = resistance measured as above and p = number of poles.

RESISTANCE OF WAVE WINDING. In measuring two-circuit series-drum windings it is necessary to measure between two commutator segments separated by a distance equal to the periphery of the commutator divided by the number of poles. This will give the effective resistance of the armature.

BRUSH CONTACT RESISTANCE. The resistance of the brushes and brush contact is calculated from data such as given in Art. 12; a measurement made with the actual circuit is not very satisfactory. However, it is sometimes the practice to measure the resistance of the entire armature circuit from brush to brush by the drop in potential method for several values of current, the armature being at rest. This is not accurate, however, as the resistance of brush contacts depends upon the speed.

SATURATION CURVE. The saturation curve is not of immediate interest in determining the quality of a machine but is more particularly of interest to the designing engineer. It is made by driving the armature at the proper speed and supplying current to the shunt fields from a separate source of potential. As the current in the shunt field increases, the potential generated by the armature varies, and this is measured by a voltmeter.

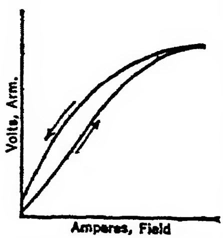

Fig. 25. Saturation Curve

On account of the existence of the hysteresis loop (see Magnetic Materials, Sect. 2, § 16), it is necessary to increase the field current gradually and never to reduce the value while changing from point to point until the maximum value has been reached. Then the field current is reduced, step by step, to zero. This gives two curves, one with "rising field current" and one with "falling field current." The curves plotted with volts as ordinates and field current or ampere-turns as abscissas show the typical knee of all saturation curves as seen in Fig. 25.

CORE LOSS AND FRICTION, OR STRAY POWER. These tests are made with the same arrangement as used in determining the saturation curve, and may be made at the same time. The machine to be tested is driven by a small motor having a capacity about 10 per cent of the rating of the machine under test. All the losses and constants of this motor must be known.

First the machine under test is driven at the desired speed with no current in the fields, and the power taken by the driving motor is noted. The mechanical output of the driving motor is calculated, and this gives the friction loss of the large machine.

Then the large machine is excited and the power to drive it is determined. This power represents the core loss plus the friction loss. Deducting the friction loss already determined, the values of the core loss for various values of excitation are found. See also Magnetic Materials.

The combined core loss and friction loss constitute the stray power loss.

LOAD RUNS. The machine is run and the excitation adjusted to give the proper voltage at no load. The load is then added and the terminal voltage noted. If E_0 = voltage at no load and E = voltage at full load, the regulation is $\dfrac{E_0 - E}{E}$.

If the machine does not have commutating poles it is necessary to make a preliminary test in order to set the brushes at that position which gives the best compromise in sparking at no load and full load. Commutation is judged by observing the action of the brushes at full load and 150 per cent load. The conclusions are a matter of judgment and experience, although degrees of sparking have been arbitrarily agreed upon and are represented in a chart or series of pictures.

HEAT RUNS are made by operating the machine at full load for a period of time until the temperatures of the various parts that can be noted during operation have become constant. The greater the capacity of the machine the longer will be the time necessary.

DEAD-LOAD AND PUMPING-BACK METHODS. Heat runs may be made either by the "dead load" method in which a resistance load, such as a water-rheostat, is connected to the terminals and full rated load power is required to drive the machine; or by the Hopkinson or "pumping-back" method in which two machines having similar characteristics are run together, one acting as a generator to supply electrical power to the motor which in turn drives the first by means of a belt or similar mechanical connection. For this test a "loss-supply" is required which may consist of a source of either electrical power or mechanical power. The amount of power required is from 10 to 20 per cent of the rating of one of the machines. The connections are shown in Fig. 26 for electrical loss supply, and Fig. 27 for mechanical loss supply.

THERMOMETER READINGS. During the heat run there are taken, at stated periods, readings of thermometers which show the temperature of the frame, field coils, bearings, and surrounding air. After the heat run the thermometers are placed on various parts of the machine, the bulbs being protected from radiation by small pads of cotton, and the following temperatures are noted:

Armature-core surface.
Armature-core ventilating ducts.
Armature conductors or winding.
Commutator surface.
Pole tips.
Field coils.
Bearings.
Frame.
Room.

The resistance of all electrical circuits should be measured and the average temperature of the copper calculated from the formula

$$= t_1 \frac{r_1}{r_0} (235 + t_0) - 235$$

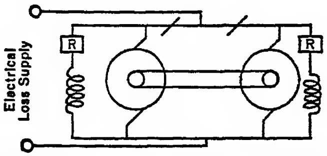

FIG. 26. Hopkinson Load Test, Electrical Supply of Losses

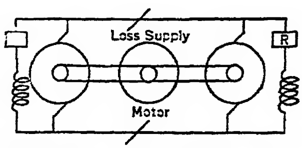

FIG. 27. Hopkinson Load Test, Mechanical Supply of Losses

where r_1 and r_0 are the hot and cold resistances respectively, and t_1 and t_0 the hot and cold temperatures respectively, 98 per cent conductivity copper being assumed. See article on Copper.

COMPOUNDING TEST. In order to adjust the current in the series field so that a compound-wound generator will give specified voltages at no load and full load, the machine is first operated at no load and the current in the shunt field is adjusted to give the desired no-load voltage. The load is then put on, and usually it will be found that at full load the terminal voltage is too great.

Strips of German silver or other resistance metal are then connected in multiple with the series field until by shunting current from the series field the voltage is reduced to such value as is desired. This shunt resistance is then made up in permanent form and connected in circuit. Before making the no-load adjustment it is desirable to overexcite the shunt field for a moment in order to overcome the hysteresis. See also Parallel Operation below.

INSULATION TESTS. Before any voltage is applied to a machine it is customary to measure the insulation resistance by means of a source of potential of 500 or 600 volts and a voltmeter reading to 600 volts. With the voltmeter in series the potential is applied between the conducting windings and to the frame of the machine.

$$\text{Insulation resistance, ohms} = \frac{E_0 - E_v}{E_v} r_v$$

where E_0 is the potential of the source, E_v is the reading of the voltmeter in series, and r_v is the resistance of the voltmeter.

The standards specify the proper values for various machines, but in general it should be more than 1/2 megohm. A lower value indicates moisture or a damaged winding.

After the heat runs it is customary to apply a high potential to test the insulation of the machine. This consists of applying an alternating potential between each electrical circuit and the frame of the machine for 1 minute. The magnitude of the potential depends upon the capacity and rated voltage of the machine under test and is definitely specified in the Standardization Rules of the A.I.E.E. (q.v.).

20. SPECIFICATIONS FOR DIRECT-CURRENT GENERATORS

The following memoranda are intended to assist in writing specifications.

PRINCIPAL CHARACTERISTICS AND CONDITIONS OF SERVICE. Service for which it is to be used, such as railway, lighting, etc. Voltage. Rated output, kilowatts. Speed.

STYLE AND DESCRIPTION, DETAILS OF CONSTRUCTION. Type, whether shunt or compound wound. Whether interpole. Details of speed and governing of prime mover and how generator is connected to prime mover, e.g., direct or belt driven by steam turbine, reciprocating engine, water wheel, water turbine, gas engine, oil engine, etc., with vertical or horizontal shaft. If field rheostat is to be supplied, its characteristics, including the effect upon the generator voltage of each step and of all steps: accessibility of armature. If belt driven, specify pulley details.

WORK TO BE DONE BY OTHER CONTRACTORS. See Alternating-Current Generators, under same heading.

PERFORMANCE AND TESTS. (See Standardization Rules of the A.I.E.E.). Temperature rises upon which ratings are to be based. Details of overload capacity. Efficiency at $^1/_4$, $^1/_2$, $^3/_4$, 1, and $1^1/_4$ loads. (Whether rheostat losses to be included in calculating efficiencies.) High potential tests of insulation. Requirements regarding effect of moisture upon insulation. When run at constant rated speed, the load may be varied from zero to a stated percentage of rated load without causing more than a stated variation of voltage, the field rheostat being kept constant.

21. INSTALLATION

In installing a d-c machine the following precautions must be observed:

1. For large machines with foundations the foundation bolts must be provided in accordance with drawings.
2. Bearings must be lined up and well cleaned before being filled with oil.
3. The armature must be properly centered so that the air gap is correct at all points. Taper wedges are used to measure the gap. The magnet frame should be bolted to the base.
4. The field coils must be properly connected. Test for polarity with a compass in order to make sure that no field coils are reversed. For a self-exciting generator there is one particular connection of the field to the armature for each direction of rotation.
5. The commutator must be smooth and polished; use sandpaper to polish the commutator, never use emery cloth.
6. The brushes must be properly and accurately spaced around the commutator. They must be sandpapered and fitted to the curvature of the commutator. The pressure on the brushes must be adjusted to the correct value which is usually 1.5 to 2 pounds per square inch of contact surface.
7. The machine must be thoroughly dried out by heating and the insulation measured as a check.

OPERATION. In starting up a single generator it is sometimes necessary to "charge" the field by separately exciting the shunt fields for a moment to set up residual magnetism.

To cause the machine to "pick up" or generate voltage by self-excitation it is necessary to cut out or short-circuit most of the resistance of the regulating rheostat connected in series with the shunt field. If the total resistance of the shunt-field circuit exceeds a certain critical value the machine will not "pick up," however much time is allowed.

The terminals of the shunt field must be connected to the terminals of the armature with a definite polarity depending upon the direction of rotation, otherwise the tendency will be to demagnetize the field rather than to build it up. This is usually found by trial and error.

PARALLEL OPERATION. In order to operate a power station under economical conditions it is necessary to have a number of machines whose aggregate capacity is equal to the maximum demand on the station. As the demand varies, the number of machines in operation is adjusted so that the machines running are operating at a load near their rating, and therefore, at a good efficiency.

SHUNT GENERATORS. In order to operate shunt generators in parallel, that is, feeding the same bus-bars, it is only necessary to adjust them all to the same polarity and voltage, connect them to the bus-bars, and adjust the division of load by strengthening the field of the underloaded machine if the voltage of the bus-bars is low. If the voltage of the bus-bars is high, weaken the field of the overloaded machine.

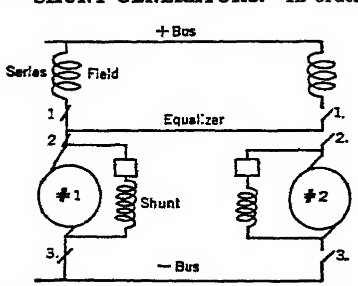

FIG. 28. Parallel Operation of Compound Wound Generators

COMPOUND GENERATORS, EQUALIZER CONNECTION. In order to operate compound-wound machines in parallel it is necessary to provide an equalizer connection which makes a common connection on all the machines at the point between the armature and the series field as shown in Fig. 28.

The function of the equalizer is to divide the load current at all times in the proper proportion between the series fields of the

different generators. This prevents the machines from acting as series generators or differential motors which would cause short circuits.

For compound-wound machines to operate successfully in multiple all machines connected to one set of bus-bars must have the same amount of compounding as well as the same voltage at no load. Owing to saturation in the magnetic circuit it is not always possible to make the compounding curve a straight line, i.e., the increase in voltage directly proportional to the load. It is, therefore, necessary to investigate the compounding curves of machines before they are operated in parallel. With unlike compounding curves one machine may become overloaded while another is underloaded, unless the field current of one machine is adjusted.

In connecting a machine in parallel with those in operation it is necessary to see that it has the proper polarity and voltage, that the equalizer circuit is made, and that the switches are closed in the order 1, 2, 3, as shown in Fig. 28. If any other order is used the effect is the same as having no equalizer.

In shutting down one machine, switch 3 must be opened first, and then 2 and 1.

22. WEIGHT AND SPEED

In Tables 10, 11, and 12 will be found the weight per kilowatt of d-c generators for usual or standard speeds. Table 10 gives the weight of a line of high-speed machines for

300	160	34,400
400	140	42,000
500	120	51,000

the suitable speeds. Table 11 gives the same information for a line of moderate-speed machines, generators or motors, and Table 12 for a line of slow-speed generators designed for direct connection to steam engines.

23. EXAMPLES OF DESIGN AND PERFORMANCE

In Tables 13 and 14 will be found the essential data including mechanical, electrical, and magnetic characteristics of four examples of d-c machines. In these data are included all the factors necessary to determine the efficiency, regulation, commutation, and heating of the machines. Dimensions are in inches and weights in pounds. Performance data are deduced from tests.

24. ELECTROSTATIC GENERATORS

In electrotherapeutic and x-ray work a unidirectional high-voltage current is desired and is often obtained by a kind of electric generator called a static generator. Two types of static generators are available for the purpose, the frictional machine and the influence machine.

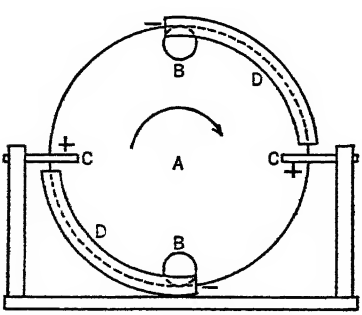

Fig. 29. Frictional Machine

FRICTIONAL MACHINE. In the frictional machine two dissimilar substances are rubbed together in some form of rotating apparatus as shown in Fig. 29. A rotating glass plate *A* is rubbed on both sides at *BB* by two pieces of leather which are greased and covered with the amalgam 1 Zn, 1 Sn, 2 Hg. The glass is electrified positively, and the charge is drawn off by the metal points *CC* which almost touch the glass. Two silk aprons *DD* cover the glass between the rubbers and the metal points, to prevent the leakage of the charge into the air. The rubbers are connected to ground to remove the negative charge which accumulates upon them.

INFLUENCE MACHINE. The influence machine generates an emf by electrostatic induction, the principle of the action being clearly shown (see Fig. 30) in a machine invented

by G. Belli in 1831. Two spheres or disks AA, called carriers, and normally insulated from each other, are rotated about the shaft B. The two fixed plates CC are charged initially from some external source. When the carriers AA take the position shown in the figure, a momentary connection is made to the neutralizing wire E at the spring contacts DD. As a result of this connection between A and A, the carriers are charged by induction, the charge on each being opposite to that of the adjacent plate. When the carriers rotate still

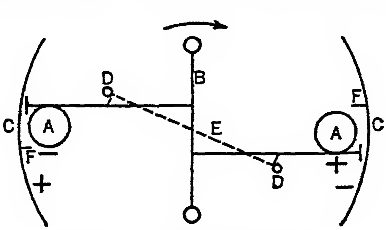

Fig. 30. Influence Machine

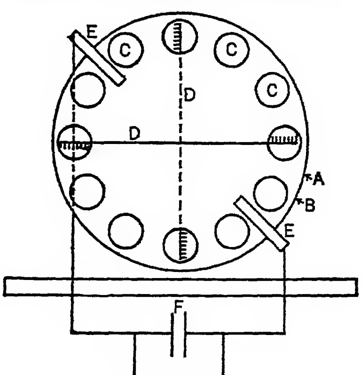

Fig. 31. Wimshurst Machine

further, the connections at DD are broken and the charges induced on the carriers become isolated. When the carriers are rotated through half a revolution from the position shown, they strike the springs FF and add their charges to the field plates CC.

WIMSHURST MACHINE. Many forms of influence machines based upon the above principles have been devised. The most successful designs were made by Toepler,

Holtz, and Wimshurst. The Wimshurst machine, shown in Fig. 31, has superseded most of the other forms because of its self-exciting powers and suitability for work in all conditions of atmosphere. Two glass disks, *A* and *B*, are rotated close together and in opposite directions. A certain number of tin-foil carriers *CCC*, are mounted upon the outside surface of each plate. Neutralizing conductors *DD* for each disk are placed at right angles to each other. The collecting combs *EE* are connected to a condenser *F* and a spark gap *G* across which the discharge takes place. If two diametrically opposite carriers on the back plate are charged positively and negatively, respectively, opposite charges will be induced upon the adjacent carriers on the front plate if they are connected by the neutralizing wire. The induced charges are isolated when this connection is broken and are drawn off at the collecting combs *EE*. In the Wimshurst machine induced charges in moving from the point of electrification to the collecting combs also serve to induce other charges on the back plate.

After a few revolutions of the disks, half of the carriers on each plate are charged negatively and half positively, giving a machine of reliable service and high power. Unlike the Holtz machine, the Wimshurst machine does not reverse its polarity when the distance between the terminals is made greater than the sparking distance. Large influence machines are constructed with several plates revolving in opposite directions and connected in parallel, the whole being contained in a glass case to protect the plates from dust. An eight-plate Wimshurst machine gives a spark of 8 in. and a twelve-plate machine will give a spark of 13 5/8 in. The plates in these machines are approximately 30 in. in diameter, and the machines give 6 sparks for each revolution of the disks.

VAN DE GRAAF GENERATOR. Very recently a new type of electrostatic generator has been developed which is designed to give 20 kw of direct current at 10 million volts. It consists of two hollow metal spheres, 15 ft in diameter, mounted upon insulating supports. Into each of these moves an endless traveling belt of silk. At the lower (ground) end the belt is electrified by friction or other means, and at the upper end a metallic brush draws off the charge and imparts it to the sphere. One sphere is charged positively and the other negatively. The spheres become charged to a very high potential and may be suddenly discharged by connection to a suitable spark gap, 40 ft at 7,000,000 volts. The device is installed at the Round Hill Laboratory of the Massachusetts Institute of Technology. It is being used in some very advanced experiments in physics, such as breaking down atoms.

For bibliography see p. 8–41.

DIRECT-CURRENT MOTORS

A motor is a dynamo-electric machine for converting electrical power into mechanical power; that is, it performs the converse function of a generator. Direct-current generators and motors are always interchangeable in function, although a machine which is designed specifically for a motor would probably not make a first-class generator, and vice versa. Motors of less than 5 hp are usually bipolar; larger machines are multipolar.

The applications of motors are treated in detail in a separate article, Industrial Applications of Motors (q.v.). The chief applications of d-c motors are the following:

Shunt Motor. Driving shafting, machine tools, blowers, reciprocating pumps; motor generators.

Series Motors. Railway and all other transportation work; hoists; cranes.

Compound Motor. Elevators, hoists, and machinery that must be started often.

Differential Motor. Very special applications of small units for peculiar speed conditions.

25. CLASSIFICATION

There are four types of d-c motors, differentiated by their characteristics and the connection of the exciting windings or circuits.

SHUNT MOTOR (Fig. 1). This motor has only one exciting winding, which is connected across the armature terminals and is thus in parallel or in shunt with the armature. The field winding consists of a large number of turns of fine wire on each pole, and usually the windings on all the poles are connected in series in one circuit. The current in the field depends upon the line voltage and upon the resistance of the field winding. The resistance of the field winding is purposely made high so that the field current will be

between 1 and 5 per cent of the full-load current of the motor. The characteristic of the shunt motor is a fairly constant speed for all reasonable values of load.

SERIES MOTOR (Fig. 2). This motor has only one exciting winding, which is connected in series with the armature so that all the current flows through the field as well as the armature. The field winding consists of a few turns of thick wire on each pole, and the windings on all poles are connected in series. The current in the field depends upon the load and is thus large with heavy load and small with light load. The resistance of the field winding is purposely made low so that the loss of voltage and power in that circuit will be small. The characteristics of a series motor are a speed varying with every change in load, high speed at light load and low speed at heavy load. The

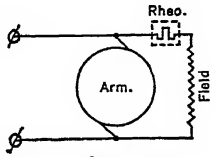

FIG. 1. Shunt Motor

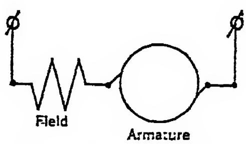

FIG. 2. Series Motor

efficiency is high throughout a wide range of speed. The speed will be dangerously high at no load; thus a series motor must always be connected rigidly to its load. Since the torque is high at low speeds this motor is particularly adapted to work requiring frequent starting.

COMPOUND (OR CUMULATIVE) MOTOR. This motor has both a series winding and a shunt winding on each pole, wound and connected so that the two windings assist each other in the production of magnetism. It is a combination of a shunt and a series motor designed to give the good starting qualities of the series motor and to avoid the danger of excessive speed at light loads. See also Industrial Applications of Motors.

DIFFERENTIAL MOTOR. This motor has a shunt and a series winding connected so that they oppose each other in the production of magnetism. The motor therefore has poor starting qualities, increases in speed with increase in load, but has no tendency to run at a dangerously high speed. The applications of this motor are very limited.

ENCLOSED VS. OPEN TYPE. These terms refer to the mechanical housing of the motor. The open type has all its parts freely exposed to the air and is therefore well ventilated. It is intended to be used indoors and in protected places. The enclosed type is intended to be used in exposed locations where there may be dampness or dirt. Special means must be provided to circulate the air inside the machine, but even then an enclosed motor is larger and more expensive than an open motor of the same capacity.

The relative capacities in output of open, semi-enclosed, and totally enclosed motors are shown by the accompanying data on one of a line of typical commercial motors. In general an enclosed motor weighs about 15 per cent more than an open motor of the same capacity in spite of the fact that it is allowed to operate at 15 deg cent higher temperature by commercial convention.

Table 1

Type	Output, hp	Temp. Rise, deg cent	Weight in pounds for 700 rpm and Given Temp. Rise
Open	10	40	970
Semi-enclosed	8	40	1000
Totally enclosed	5.75	55	1100

26. RATINGS

See Standardization Rules of the A.I.E.E. for limiting rise in temperature and for classification of types, Constant Speed, Multispeed, Adjustable Speed, and Variable Speed.

The National Electric Manufacturers Association, which includes representatives of most of the manufacturers of electric machinery in the United States, has standardized, for commercial practice, certain temperature ratings which are based on the A.I.E.E. rules. These regulations, which are for limiting temperatures as measured by thermometer with continuous duty, and the corresponding A.I.E.E. rules are:

Table 2

	Max. Rise on Commutator	Max. Rise on Other Parts
Open type	45° C	40° C
Protected type	55	50
Enclosed type	60	55
A.I.E.E. Rules	55	50

VOLTAGE AND CURRENT. Usual values of voltage for d-c motors are:

110–125 for small motors on lighting circuits.
220–250 for motors in factories, shops, etc.; on power mains or on the outside mains of a three-wire system.
500–600 for general railway work.
1200 for special railway installations.

The current required for any motor is found by the relation

$$\text{Current} = \frac{\text{Output in hp} \times 746}{\text{Efficiency} \times \text{Voltage}}$$

Usual values for the efficiencies of motors of various sizes are given below.

27. PRINCIPLES

The principles upon which a d-c motor operates are the same as those upon which a d-c generator operates (see Direct-current Generators). These principles are briefly as follows:

FORCE ACTING ON CONDUCTOR. A conductor of length l carrying a current I and placed in a magnetic field having a flux density B is acted upon by a force which is proportional to BlI, which force is in a direction at right angles to the direction of the magnetic flux and at right angles to the length of the conductor.

This in practical form gives the relation

$$T = \frac{p\phi ZI}{852\, m \times 10^6}$$

T = torque of an armature in pounds at 1-ft radius.
p = number of poles.
m = number of armature paths between brushes.
ϕ = flux per pole in armature (lines).
Z = number of active conductors or inductors on armature.
I = current taken by the armature from line.

This torque is exerted whenever a current flows and is independent of the speed. The core-loss and friction absorb some of the torque so that the torque at the pulley is slightly less than the value given by the formula.

COUNTER EMF IN CONDUCTOR. A conductor of length l moving with a velocity V in a magnetic field of density B has induced in it an electromotive force E proportional to BlV. In practice as soon as the armature starts to move a counter emf is induced in its conductors which has the value

$$E = \frac{p\phi Zn}{m \times 10^8}$$

when n = revolutions per second.

Thus as soon as the armature moves, this counter emf tends to stop the flow of current and the impressed emf must be increased to maintain the flow of current.

The relation between current and counter emf is given by the equation

$$E_i = E + IR$$

where E_i = impressed emf; E = counter or generated emf; and R = resistance of armature circuit.

In practice R is made as small as possible so that E and E_i are as nearly equal as possible.

REVERSING ROTATION. From a consideration of the equation for the torque it is evident that torque is proportional to the product ϕI, i.e., to the product of the flux in the armature by the current. If the direction of the current through the armature is reversed, that is, if I becomes negative, the product becomes negative and the torque is in the opposite direction. If the direction of the flux is changed (the armature current

being unchanged) the direction of torque is reversed. But if both ϕ and I are reversed the torque is not reversed. From this follows the rule for reversing the direction of rotation of any d-c motor; viz., change the direction of flow of current in either the field or armature winding but not in both.

SPEED CONTROL. From the equation for counter emf it follows that the speed is proportional to E/ϕ. That is, the speed varies directly as the counter emf and inversely as the flux. Thus to reduce the speed, decrease the counter emf by decreasing the emf impressed on the armature or increase the flux by increasing the field current. To increase the speed perform the converse. To decrease the emf impressed on the armature, a resistance may be inserted between the source of potential and the armature terminals. This is the customary manner of controlling the speed during the starting of motors. (See also below on Starting of D-c Motors.)

28. SHUNT MOTOR

Since the flux in the armature of a shunt motor is practically independent of load, the characteristics of the motor are: approximately constant speed for all reasonable variations of load, torque directly proportional to the armature current irrespective of speed, efficiency high throughout, a wide range of load but for only a small range of speed, see Fig. 3.

DESIGN OF SHUNT MOTOR. The method of design and calculation of shunt motors is the same as for d-c generators (see Direct-current Generators) except for the minor details noted below.

The armature reaction of a motor is in the opposite direction to that of a generator running in the same direction, and thus the field is distorted in the opposite direction. Hence, if the brushes are to be moved to assist commutation, they must be moved in a direction opposite to the direction of rotation of the armature.

The effect of armature reaction is to weaken the field. This causes a tendency to increase the speed and also causes bad commutation.

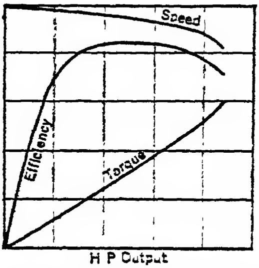

Fig. 3. Speed, Torque, and Efficiency Characteristics of a Shunt Motor

The stability factor of a motor must be greater than that of a generator because when the motor drops in speed as the load comes on, the field must be weakened to increase the speed. Hence the field is liable to be operated at an excitation less than normal.

TESTING OF SHUNT MOTORS. (See also Standardization Rules of the A.I.E.E.). The tests on shunt motors may be divided into two classes: (*a*) commercial, to determine the qualities and serviceability of particular motors; and (*b*) special, to determine the general characteristics and actions of a type of motor. Commercial tests are the following:

Resistance measurements.
Stray power test, including core loss and friction.
Input-output test for heating, efficiency and commutation.
Insulation test.

RESISTANCE MEASUREMENTS are made with the machine cold and later after the heat run. The resistances of the armature winding and field winding are measured, and the brush-contact resistance may be measured but is usually calculated (see Direct-current Generators). For any value of current the resistance losses (RI^2) are calculated from the measured hot resistances.

"STRAY POWER" TEST. The term "stray power" is applied to the lumped sum of the core loss and the loss due to friction, bearings, and windage. The stray power of a d-c machine can be determined approximately by impressing normal voltage on the field and letting the machine run as a motor without load, varying the voltage impressed on the armature from about 10 per cent above normal to about 10 per cent below normal. The speed, armature voltage, and armature current for each adjustment are observed. Then the stray power for any induced voltage is equal to the armature input less the corresponding RI^2, where R is the armature resistance and I the armature current. The value of stray power for any given load on the motor is then equal to the measured value corresponding to the same counter emf E, where E is calculated from the impressed voltage E_i by the relation $E = E_i - RI$.

If it is desired to determine the stray power more accurately by taking into account the effect of armature reaction, the field current may be adjusted so that the speed on

the above run is the same as the load speed. This gives a flux of the same average value as when the machine is under load.

CALCULATION OF EFFICIENCY FROM LOSSES. Let P = total output in kilowatts; R_a = resistance of armature, including brushes; I_a = armature current; I_f = field current; E_i = impressed voltage; S = stray power. Then the per cent efficiency is

$$\epsilon = \frac{100\,P}{E_i(I_a + I_f)} = \frac{100\,P}{P + E_i I_f + I_a^2 R_a + S}$$

INPUT-OUTPUT TEST WITH PRONY BRAKE. The input-output test may be made either by means of a prony or band brake on a pulley, or by using a d-c generator as a load. If the brake test is made the output is

$$\text{Watts} = \frac{PLN}{7.04}$$

where P = net pull in pounds, L = lever arm or radius in feet, N = revolutions per minute.

INPUT-OUTPUT TEST WITH GENERATOR AS LOAD. With large motors it is desirable to use a generator as a load in making an input-output test. In this case it is necessary to know the resistance of the generator armature circuit. It is also desirable to have the generator separately excited and to maintain a constant excitation throughout the entire test.

The input of the motor and the output of the generator, together with the speeds of both machines, are observed. A "counter-torque" test must also be made to determine the belt friction loss and the core loss and friction of the generator. This is performed by making two tests as follows:

(*a*) The motor input is observed when driving the unloaded generator at normal speed first through the regular leather belt and second through a light cotton belt. The difference in input to the motor in the first and second cases gives the belt-friction loss. As this loss is comparatively small, it may frequently be neglected.

(*b*) A regular stray power test (see above) is made on the generator when entirely disconnected from the motor. This gives the core loss and friction of the load machine (generator).

Then for any load during the load run the output of the motor under test is

$$P_1 = P_2 + R_2 I^2 + S + F$$

where P_1 = output in watts of motor, machine 1.
P_2 = output in watts of generator, machine 2.
$R_2 I^2$ = loss in armature winding of generator.
S = stray power of generator for speed and induced voltage at observed load.
F = belt-friction loss.

The ratio of this motor output to the electrical input as observed gives the efficiency of the motor.

HEAT RUN. From the input-output test it is also possible to determine the speed regulation, commutation features and heating. The heat run may also be made by "bucking" two machines as described in the article Direct-current Generators. Small motors will reach a constant temperature in a short time, and the heat run need only last 5 or 6 hours for a 100-hp motor. A thermometer is usually placed on the machine in a safe and accessible place and read every half hour until it indicates no further rise in temperature.

INSULATION TEST. The margin of safety on a 110- or 220-volt motor is usually so great that it is not necessary to make an insulation test. If the motor has been exposed to dampness it may be desirable to make the test after the motor has been thoroughly dried out. The method is indicated in the Standardization Rules of the A.I.E.E. (q.v.).

SPECIAL TESTS. As a special test there may be obtained a saturation curve of the machine and possibly the distribution of potential around the commutator. These are of particular interest in an adjustable-speed motor. In some of these motors with commutating poles there may exist some very high voltages between bars which are not evident except in the bar-to-bar potential test.

29. SERIES MOTOR

Since the flux in the series motor is produced by the load current, the flux increases with the current. The torque is proportional to the product ϕI and therefore increases more rapidly than the current. Thus four times full-load torque can be obtained with from two to three times full-load current.

The characteristics of the series motor are: increase of torque faster than increase of current, variation in speed inversely as the load, and high efficiency throughout a wide range of speed as well as load; see Fig. 4.

DESIGN OF SERIES MOTORS. In general the method of calculation is the same as for a direct-current generator (see Direct-current Generators). The special considerations are:

A series motor is usually designed to have a large output and low speed at the 1-hour rating. At any lesser output the speed will be higher, so the peripheral velocity must be quite moderate at the rated load and speed.

Since the speed is very nearly inversely proportional to the flux the speed curve depends on the shape of the saturation curve, to which very careful attention is paid in designing. By exactly fixing the flux for two extreme values of current the speed for these two values of current is fixed.

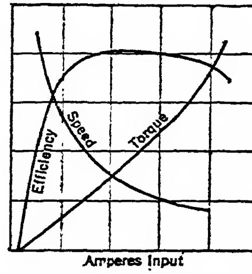

FIG. 4. Speed, Torque, and Efficiency Characteristics of a Series Motor

The relations between the speed and current of a series motor are shown by the formulas:

$$E_i = E + IR$$

$$E = \frac{p\phi Zn}{m\,10^8}$$

$$n = \frac{m(E_i - IR) \times 10^8}{p\phi Z}$$

where E_i = impressed voltage.
E = counter emf induced in armature.
R = total resistance of armature and field.
I = current taken by motor.
p = number of poles.
m = number of parallel paths between positive and negative brush sets.
Z = total number of conductors on armature.
n = speed of armature in revolutions per second.
ϕ = total flux per pole in maxwells.

Since the current in the field of a series motor is the same as that in the armature, the ratio of the turns in each is the same as the ratio of ampere-turns or mmf's. Thus if the mmf per pole of the field is to be 1.5 times that of the armature the number of turns will be 1.5 times the number of turns in series in the armature.

Since a series motor is usually an enclosed motor with a 1-hour rating its rise in temperature and rating are a direct function of the watts lost and the ability of the mass of the motor to store up this heat energy. In a 1-hour run the amount of energy radiated is only about 10 per cent of the amount stored in the mass. For a rise in temperature of 75 deg cent in 1 hour there should be about 0.4 lb of material for each watt of loss. This assumes reasonable provision in the construction of the motor for the transfer of the heat from the armature to the field and frame.

Much attention has been directed recently to the ventilation of these motors by drawing air from outside the motor by means of fan blades on the armature and by circulation of the air inside the motor through definite paths. This has considerably increased the weight efficiency of these motors.

In railway motors, which are the most general application of the series motor, commutating poles are very generally used, as this construction makes it possible to obtain a much greater momentary output from a motor of a given size (see Table 3).

Table 3. Design Constants of a Typical Series Motor for Railway Service

Rated horsepower, 1 hr.	50	Commutating pole turns	58
" voltage	600	Armature reaction, amp-turns per pole	3750
" current	80	Magnetic density in gap	34,000
" rpm	660	Amp × conds per inch, sigma	720
Number of main poles	4	Friction inc. gearing, watts	2400
" " commutating poles	2	Core loss	4000
Armature diameter × length	13.25 × 14	Copper loss	4400
" slots	25	Efficiency inc. gears, at rating	77.5
" conds over slot	30	Resistance of armature	0.322
" winding	S.D.	" " main field	0.190
Useful flux per pole	3.3×10^6	" " commutating field	0.139
Field turns per pole	60	Weight of motor, lb	2600

TESTING OF SERIES MOTORS. (See also Standardization Rules of the A.I.E.E.) To determine properly the speed and torque characteristics of a series motor an "input-output" test must be made, which involves subjecting the motor to actual load and overload conditions. This may be accomplished by running the motor with a prony brake as a load or with a direct-connected generator as a load (see above on Testing of Shunt Motors).

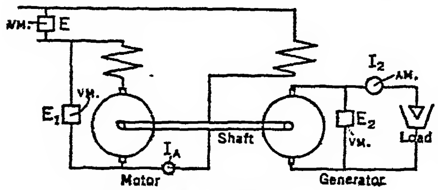

FIG. 5. Railway Motor Load Test

RAILWAY MOTOR TEST. When two similar motors are available the method used by the manufacturers of railway motors is most desirable. The two motors are direct connected, or geared to each other, and the electrical connections made as in Fig. 5. The test is run through by keeping constant rated voltage on the motor and regulating the load on the motor by changing the load on the generator.

As the two machines are operating under almost exactly the same conditions, their efficiencies are very nearly the same. Thus

$$\text{Efficiency of set} = \frac{E_2 I_2}{EI}$$

$$\text{Efficiency of each motor} = \sqrt{\frac{E_2 I_2}{EI}}$$

The speed and torque curves should be made for both directions of rotation of the armature as an incorrect brush setting will give results differing with the direction of rotation. The direction of rotation is changed by reversing the connections of either the field or the armature of the motor.

Commutation is observed during the speed and torque test.

The heat run is made with the same arrangement as the speed-torque test. In making the heat run the motor must start cold or at room temperature. The covers of the inspection openings of railway motors are customarily left open during the heat run.

LOSSES AND EFFICIENCY OF SERIES MOTORS. For a more accurate determination of the efficiency and losses the following special tests are made:

1. Resistance of armature, brushes and field. These tests are similar to those for a shunt motor, see above.

2. Core-loss test. On account of the variable speed and variable field of a series motor this test consists in repeating the usual core-loss test as described above for a generator at several different speeds. The field strength is varied step by step throughout the maximum range for each speed. Fig. 6 shows the curves for these different runs and the dotted line connects the points on the different curves that apply to the normal speed curve of the motor.

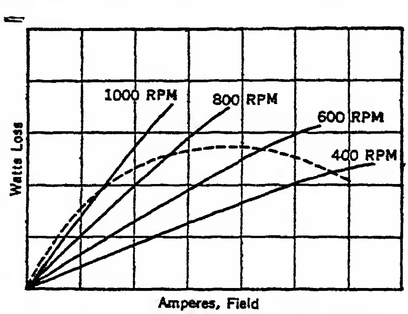

FIG. 6. Core-loss Curves of Series Motor

INSULATION TESTS. See Direct-current Generators and Standardization Rules of the A.I.E.E.

30. STARTING OF DIRECT-CURRENT MOTORS

A starting box, Fig. 7, or rheostat is always employed in starting d-c motors in order to reduce the voltage impressed on the motor when it is not running at a high enough speed to generate the proper counter emf.

Let E_t = line voltage.
I_0 = armature current at full load.
N_0 = speed at full load (shunt motor).
E_0 = counter emf at full load.
I = 1.5 I_0 usually accepted peak starting current.
r = resistance of the armature circuit.
R = resistance of starting box or rheostat.
E = counter emf at any other speed.

Then, in general:

$$\text{Current } \frac{E_i - E}{r + R} \quad \text{and} \quad N = \frac{N_0 E}{E_0}$$

The total resistance in the rheostat on the first step should be:

$$R_1 = \frac{E_i}{I} - r$$

the counter emf at the end of the first step

$$E_1 = E_i - I_0 (R_1 + r)$$

and the constant speed:

$$N_1 = \frac{N_0 E_1}{E_0}$$

For the second step the total resistance in the rheostat should be:

$$R_2 = \frac{E_i - E_1}{I} - r$$

At the end of the second step:

$$E_2 = E_i - I_0 (R_2 + r) \quad \text{and} \quad N_2 = \frac{N_0 E_2}{E_0}$$

Succeeding steps are determined until the value of R_2 decreases to zero. In general for $I = 1.5\, I_0$, we have $1.5\,(R_2 + r) = (R_1 + r)$ and $R_n = 2/3 R_{n-1} - 1/3\, r$.

Fig. 8 shows the sudden rise in current when the resistance is changed and the gradual decrease in current as the speed increases. The number of steps necessary depends upon the ratio of the maximum allowable instantaneous value of the current to the final constant value, upon the value of the armature resistance, and upon the inertia of the load.

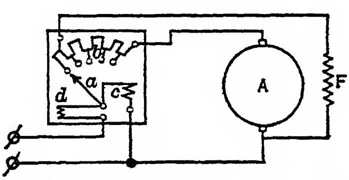

FIG. 7. Starting Box Connections for Shunt Motor

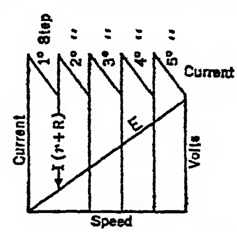

FIG. 8. Motor Current During Starting

STARTING BOX. (See also article on Rheostats.) A starting box usually contains the following features, as indicated in Fig. 7: (*a*) a means of opening and closing the circuit supplying all the current to the motor including the field current; (*b*) a set of resistance steps in series with the motor armature and a means of short-circuiting this resistance step by step; (*c*) a magnet coil connected across the motor terminals to open the circuit if the impressed voltage fails or falls below a specified value (low-voltage release); (*d*) a magnet coil carrying the main current to actuate a spring and open the circuit if the current exceeds a specified value (overload release). The usual connections of a starting box to the line and motor are shown in Fig. 7.

31. SPEED CONTROL

There are three methods of varying and controlling the speed of d-c motors, namely, potential, rheostatic, and field systems.

POTENTIAL CONTROL OR MULTIVOLTAGE SYSTEM. By means of several generators and several wires various definite voltages are made available, such as 240, 180, 120, etc. By connecting the motor to the 240-volt circuit, full speed is obtained; by connecting to the 180-volt circuit, $^3/_4$ speed is obtained, etc. The shunt field circuit is left connected at all times to a circuit of the proper voltage. A shunt motor with normal field excitation will be stable, that is, it will operate constantly, at the fractional speed. The efficiency will be good at the fractional speeds. A series motor controlled in this manner will be unstable, but for a given torque the speed will be roughly proportional to the voltage.

RHEOSTATIC CONTROL. A rheostat in series with the armature will reduce the voltage impressed on the armature by an amount proportional to the current, and thereby

reduce the speed. The speed is unstable with this arrangement, changing with every change of load, and the efficiency is poor.

FIELD CONTROL. By increasing the resistance in series with the field of a shunt motor the speed is increased due to the weakening of the field. If the motor has commutating poles to assure good commutation the speed may be varied in a ratio of 1 to 2, and even 1 to 3 in small sizes. The shunt motor is stable with this method of control and the efficiency is good. In a series motor the field may be shunted by a resistance to increase the speed but the motor is not stable and this practice is not to be recommended.

32. USE OF COMMUTATING POLES (INTERPOLES) IN VARIABLE-SPEED MOTORS

In motors intended to be operated over a large variation in speed, obtained by changing the field strength, and in motors which are to be subjected to heavy overloads, it is necessary to use commutating poles in order to obtain good commutation. In a motor without commutating poles the field strength must always be a certain percentage greater than the armature strength to prevent a shifting of the field flux and of the neutral point. Thus, if, in Fig. 9, F represents the distribution of field flux when existing alone and A represents a strong armature flux existing alone, then R shows the distribution of the resultant flux when both field and armature are excited.

It will be noticed that the neutral point has been shifted from XX at no load in a direction against rotation to YY at the load considered. The brushes would have to be shifted from XX at no load to a point ZZ beyond YY at load in order that they shall commutate a coil in a flux which is producing a voltage helpful to commutation.

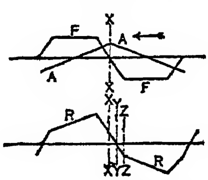

Fig. 9. Flux Distribution without Commutating Poles

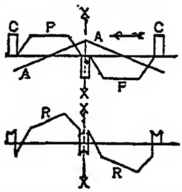

Fig. 10. Flux Distribution with Commutating Poles

RESULTANT FLUX WITH COMMUTATING POLES. If, however, commutating poles are placed between the main poles and excited with the armature current, they will maintain at the geometrical neutral a flux of the direction and value necessary to give good commutation. In Fig. 10, F and A represent the field and armature flux separately as before and C the commutating pole flux that would exist at full load. When at full load these fluxes are combined, there exists the resultant flux shown at R.

It will be noticed that there remains at the neutral point a small flux of the proper polarity and magnitude to provide an emf to reverse the current and give good commutation, and it is not necessary to move the brushes.

The commutating pole must be of the same polarity as the pole towards which the brush would have to be moved if there were no commutating poles. In fact, the principle of commutating poles is nothing more than bringing to the brush a part of the pole instead of moving the brush to the pole. Thus the polarity of the commutating pole is different during motor action from that during generator action. If the windings on the commutating poles are connected in series with the armature the conditions will be correct for either motor or generator action. See p. 8–17.

33. INSTALLATION AND ERECTION

In the installation and erection of a d-c motor there are certain features which must receive careful attention in order that the machine shall operate properly and not deteriorate with undue rapidity. Although this procedure varies with different motors according to their mechanical construction the following brief memorandum of points to be looked after will be found useful:

1. Base bolted down.
2. Bearings clean and filled with oil.
3. Bearings lined up.

4. Magnet frame bolted to base.
5. Field coils secured in place.
6. Field coils tested for open circuit, wrong connection, and polarity.
7. Armature in place.
8. Air gap adjusted by shimming.
9. Measure resistance of armature and field.
10. Measure insulation resistance.
11. Brushes properly fitted and spaced and pressure adjusted to about 1.5 to 2 lb per brush.
12. Commutator smooth and true.
13. Substantial connections of field circuit.
14. Field adjusted for correct direction of rotation.

The motor must be protected from moisture during shipment and if by accident it becomes damp it must be dried out before it is subjected to a voltage.

34. OPERATION

In the operation of a direct-current motor several factors should be considered.

CARE. All motors should be frequently inspected and the following points noted:

1. Bearings filled with proper amount of oil.
2. Brushes securely held in proper position.
3. Brushes fit properly.
4. Commutator smooth: danger of "high mica" or the insulation between commutator bars projecting above the bars.
5. Air gap true.
6. Commutator not worn in grooves.

TROUBLES. In the following paragraphs is given a concise list of the troubles that may be experienced in operating d-c motors and their causes as given by Crocker and Wheeler in Management of Electrical Machinery.

1. *Sparking at the Commutator.* Causes: Armature carrying overload. Brushes improperly spaced. Brushes not at proper position. Rough commutator. Poor brush contact. Internal short or open circuit. Field too weak. Unequal strength of poles. Vibration.

2. *Heating of Commutator and Brushes.* Sparking. Bearing trouble. Bad connections. Brush friction too great.

3. *Heating of Armature.* Overload. Internal short circuit, moisture or ground. Reversed coil. Excessive eddy currents.

4. *Heating of Field.* Internal short circuit.

5. *Heating of Bearings.* Bearings dry or dirty. Shaft out of true. Bearings out of line. Thrust due to belt. Unbalanced magnetic pull.

6. *Noise.* Armature not balanced. Brushes dry or not set at proper angle. Armature strikes.

7. *Speed Too Low.* Wrong voltage. Overload. Armature strikes. Bearing too tight.

8. *Speed Too High.* Wrong voltage. Field too weak.

9. *Motor Stops or Fails to Start.* Overload, open circuit, wrong connection.

35. SPECIFICATIONS

DIRECT-CURRENT MOTORS FOR INDUSTRIAL USE (*See also Specifications for Railway Motors.*) The following memoranda are intended to assist in writing specifications.

Principal Characteristics and Conditions of Service. Use to which motor is to be put, kind of load and method of drive. Voltage. Rating, horsepower. Speed.

Style and Description; Details of Construction. Whether to be open, semi-enclosed, or enclosed. Whether to be series, shunt, or compound wound; if shunt wound, whether shunt field rheostat is to be supplied; if compound wound, state whether cumulative or differential. Requirements regarding pulley or length of shaft. Whether rails are required. Whether starting rheostat is to be supplied, and if so, its general characteristics.

Performance and Tests. (See Standardization Rules of the A.I.E.E.) Temperature rises upon which ratings are to be based. Details of overload. Efficiency at 25, 50, 75, 100, and 125 per cent load; whether rheostat losses are to be included in calculating efficiencies. Starting torque with full-load current, pound-feet. High-potential tests of insulation. Requirements regarding effect of moisture upon insulation. Regulation; the supply voltage being constant, and the field rheostat fixed, a variation of load from zero

to ... per cent of full-rated load shall cause a variation of speed not greater than ... per cent. The shunt field rheostat to give speed variation of ... per cent in steps not greater than ... per cent and not less than ... steps, and to carry the current for any speed continuously without undue heating.

SERIES RAILWAY MOTORS. The following memoranda are intended to assist in writing specifications.

Principal Characteristics and Conditions of Service. General statement of the service, giving type of cars, whether current is direct or alternating, or both, etc. The motor shall be designed for normal operation at ... volts and shall operate safely at ... volts.

Style and Description; Details of Construction. The frame shall be designed so as to allow the easy removal of armature and field coils. It shall be provided with openings at both ends, and both above and below the shaft, which will enable the inside of the motor to be readily inspected and cleaned. Bearings shall be designed so that lubricant cannot enter the frame, and shall be so located that they may be easily emptied and cleaned. The diameter of the driving axle on which the motor is to be mounted shall be ... inches. Whether motor is to be of interpole type. Whether natural or forced ventilation.

Brushes and Brush Holder. The brush holders shall be readily removable through the hand holes. The springs holding the brushes against commutator shall not be relied on to carry current. The brushes shall be staggered or provided with adjustment parallel to the armature shaft so as to prevent the formation of ridges on the commutator.

Clearances. The minimum distance between motor frame and back of wheel flanges shall be ... inches, the minimum distance between bottom of motor and top of rail when tires are new shall be ... inches.

Gears and Gear Case (if any). Single or double reduction; what gear wheels shall be mounted on; material of wheel and pinion; description of teeth, whether cut or cast, and width of face of wheel or pinion; gear case material, how suspended, oil-tightness.

Suspension of Motors. General description and requirements, location of lugs on motor frames.

Data to be Furnished by Bidder. The armature will be bound with ... bands. Material and dimensions of the bands. Dimensions of openings in the frame. The brush holders will be adjustable so as to allow ... inch wear with uniform pressure on the brushes, after the diameter of the commutator has been reduced by ... inches. The current density in the carbon brushes will not exceed ... amperes per square inch at normal rated load. The gear ratio will be ...

Performance and Tests. (See also Specifications in article on Electric Locomotives.) Either the nominal rating and the continuous ratings at $^1/_2$, $^3/_4$, and full voltage should be specified, or the following data supplied:

Line voltage ....
Number of motors per car ....
Weight of loaded car, exclusive of motors and control equipment ....
Diameter of driving wheels ....
Schedule speed ....
Distance between stops ....
Duration of stops ....
Acceleration, miles per hr per sec ....
Retardation, miles per hr per sec ....

The engineer should also give a diagram of grades and curves.

Motor Characteristics. The bidder shall submit diagrams showing speed, tractive effort, efficiency, RI^2 losses, core losses, and any other information bearing on the performance of the motor. Requirements regarding the effect of moisture upon insulation.

Tests. The motor shall be tested at the manufacturer's works in the presence of the engineer's inspector. (In the case of new motor developments it is good practice to make the tests under service conditions; but for standard motors a stand test at the factory is sufficient.) A complete series of tests shall be made upon the first motor manufactured under this specification. These tests shall confirm all the statements made by the bidder in relation to operating characteristics. Should the motor fail to comply with any of these statements, the defects shall be corrected and any changes in construction or design which may be necessary to accomplish this shall be made at the contractor's expense. The first motor shall be submitted to a flashing test to determine the susceptibility of the motor to flash over on opening the maximum specified line voltage across the motor when running at maximum speed. After the acceptance of the first equipment, any other motors to be supplied under this specification shall be submitted to an approved stand test. The insulation of the armature windings, commutator and field windings, shall be subjected to stated alternating voltages (see Standardisation Rules of the A.I.E.E.) for a period of 1 minute.

36. PERFORMANCE, WEIGHT, AND SPEED

Usual values of the efficiency and losses, and also values of the weight and speed of shunt and series motors are given in the following tables:

Table 4. Performance of Shunt Motors

Hp	Full-load Efficiency, per cent	Field I^2R, per cent	Friction, per cent	Core Loss, per cent	Armature I^2R, per cent
0.5	70	5	10	5	10
1	79	4	8	4	5
2	82	3.5	7	3.5	4
5	85	3	5	3	4
10	87	2.5	4.5	2	4
20	88	2	4	2	4
25	89	2	3	2	4

Table 5. Weight and Speed of Shunt Motors

Hp	Moderate Speed		Slow Speed	
	Speed, rpm	Weight, lb	Speed, rpm	Weight, lb
0.5	2200	55	....	....
1	2000	105	1675	125
2	1750	200	1175	250
5	1100	470	925	600
10	850	880	700	1100
20	680	1550	550	1900
25	650	1900	500	2300

Table 6. Performance of Series Motors
Commutating Pole Railway Type

Hp*	Full-load Efficiency, per cent	Field I^2R, per cent	Friction, per cent†	Core Loss, per cent	Armature I^2R, per cent
40	79	6.5	5.3	2.2	7.0
50	82	5.0	5.0	2.1	5.9
75	84	4.5	5.0	2.0	4.5
100	85	4.3	5.0	2.0	3.7
150	86.5	3.5	5.0	2.0	3.0

* Horsepower for 75 deg cent rise in 1 hr.
† Friction includes loss in gearing.

Table 7. Weight and Speed of Series Motors
Commutating Pole Railway Type

Hp*	Speed, rpm	Lb, weight per hp †
40	850	50
50	800	48
75	725	40
100	700	35
150	650	30

* Horsepower for 75 deg cent rise in 1 hr.
† Weight includes cast-steel frame and gear pinion and gear case.

Design constants of some d-c motors are given on p. 8-28 under Direct-current Generators.

ALTERNATING-CURRENT MACHINES

by Walter I. Slichter

ALTERNATING-CURRENT GENERATORS

In all dynamo-electric machines of the usual forms (excepting the homo-polar) the electromotive force induced in any one conductor or turn varies in value and alternates in direction. If the terminals of any coil or group of coils are brought out to an external circuit by means of revolving contacts, such as slip-rings, an alternating current will flow in the circuit. In order to obtain a direct or continuous current it is necessary to add a commutator or rectifier. Thus the most simple and elementary form of electric generator is an a-c generator, and the d-c generator is a special form adapted by the addition of a commutator to give a continuous or unidirectional current.

1. CLASSIFICATION

Alternating-current generators may be classified according to several different distinguishing characteristics. The following classification considers these characteristics in the order of their prominence.

Synchronous Generators. In the synchronous type the action of inducing the electromotive force results from the relative motion of the armature conductors and a constant magnetic field produced by exciting coils in which a continuous or direct current flows. The frequency of the alternating electromotive force depends directly on the number of field poles and the angular velocity of the revolving part.

Induction Generators. In the induction type the magnetic field is of the rotating polyphase type and is produced by polyphase alternating currents flowing in the same windings with the load current. The mechanical construction is usually that of an induction motor with a short-circuited polyphase winding on the revolving member. The frequency depends upon the characteristics of the external circuit. In practice the frequency is determined or " set " by a synchronous machine, either generator or motor, in the external circuit. This " frequency setter " is necessary to supply the exciting current of the induction generator; that is, by means of the frequency setter the power factor of the total load is adjusted to equal the inherent power factor of the generator.

A minority of the units of a station may be of the induction type with advantage as they will cause less disastrous effects in case of a short circuit on the system. Their instantaneous short-circuit current is less. A certain number of the units must be of the synchronous type to " set " the frequency and supply the exciting current for the induction machines. Consequently, if there is a large proportion of induction machines the synchronous machines operate at a poor power factor unless there is much capacitance effect in the load system, such as synchronous motors or line capacitance.

Revolving-field and Revolving-armature Types. In the revolving-field or revolving-armature type there are two, or some multiple of two, poles, each pole having its own coil for the d-c excitation, and the flux in each pole is to all intents and purposes constant in value. The relative movement of the poles and conductors causes the variation in flux interlinkages both in direction and intensity.

The early machines were constructed with an armature revolving inside a stationary field. As sizes and voltages increased it was found that a more effective use of the material could be obtained by making the armature the external member, and that the insulation of the high-voltage member was better preserved if that member was kept stationary.

At the present time all generators of large capacity (500 kw and greater) and for high voltages (600 volts and up) are made of the revolving-field type.

Inductor Type. In the inductor type the d-c excitation is concentrated in one (usually stationary) coil, and the variation in magnetic flux is obtained by revolving a spider with bare projecting poles which alters the reluctance of the magnetic path. Thus the flux threading any particular armature coil is always in the same direction, but varies in intensity or quantity.

There are no windings or insulation on the moving member of the inductor type,

which is therefore adapted to high speeds. The greater variation in the reluctance of the main magnetic path and the consequent variation in magnetic densities in the field structure of the inductor cause excessive eddy currents, hence the construction of this type has been abandoned for machines of large power.

Single Phase, Two Phase or Quarter Phase, and Three Phase. The single-phase generator is usually about 50 per cent heavier and more costly than a polyphase generator of the same rating. By changing the internal armature connections a polyphase machine may frequently be reconnected to be a three-, two-, or single-phase machine.

As transmission by three-phase currents is more economical of copper than by two-phase or single-phase currents, all power transmission lines are three-phase. Consequently unless there is some local condition requiring single- or two-phase, the three-phase generator is preferable.

Two-phase and three-phase generators of the same capacity and voltage strain are of practically the same dimensions, weight, and cost.

Separately Excited and Self-excited Types. For years it was attempted to develop a satisfactory and simple self-excited alternator, and some were very successful but not simple. The object was to obtain a constant voltage on the load by means of automatic self-excitation. However, with the perfection of the automatic voltage regulator the need for automatic self-regulation ceased, and there is now very little demand for self-excited alternators.

METHODS OF RATING. All a-c generators are rated in kilovolt-amperes (kva) and unless otherwise specifically stated are rated at that kva which they will give continuously with a rise in temperature not exceeding certain values depending upon the character of the insulating materials used; see Standardization Rules A.I.E.E.

Machines, or those parts of machines, insulated with mica, asbestos, or similar heat-resisting material, are allowed a rise in temperature of 70 deg cent as measured by thermometer, or 75 deg if measured by resistance. This includes most turbo-alternators, both armature and field, and the fields of many other alternators.

Machines, or those parts of machines, insulated with varnished cambric or impregnated cotton or linen, are allowed a rise of 50 deg cent as measured by thermometer, or 55 deg if measured by resistance. This includes the armatures of most slow and moderate speed machines.

Most machines have their fields designed sufficiently liberally to enable them to give their rated kva at 80 per cent power factor with rated voltage, and this is stated in the specifications. It should be noted that the heating of the *armature* depends upon the kva and not upon the kilowatt load. The lower the power factor of the load connected to the alternator, the greater the heating of the *field coils* for the same kva output.

VOLTAGE. Alternators are now built to generate voltages up to 22,000 and 30,000 volts between lines, either single phase or polyphase. Above that voltage the extra cost of the insulation and the danger of damage from discharges cause it to be less expensive to install transformers with a lower voltage alternator. Some engineers consider the limit of economical voltage of generators to be even lower than 22,000 volts.

FREQUENCY. The frequency depends upon the speed of rotation and the number of poles. If the speed of rotation of the revolving part is given in revolutions per minute, the frequency is

$$f = \frac{\text{rpm}}{60} \times \frac{\text{Number of poles}}{2}$$

In the early alternators it was found much more economical to run at high speeds, and thus high frequencies such as 133 and 125 cycles per second were customary; but, as systems increased in size and complexity, electrical difficulties arose as a result of these high frequencies, and the tendency has been to reduce the frequency till now we have 60, 50, 40. and 25 cycles per second as usual frequencies, of which 25 and 60 are standard in this country. In Europe 50 cycles is used instead of 60, and 15 or 16 cycles for railway work.

A frequency of 25 cycles is preferable where there is a very long transmission line, on account of the lower inductive voltage drop, and where there is much synchronous machinery, such as synchronous motors and rotary converters, as these are more stable and better adapted to parallel operation at low frequencies.

A higher frequency (60 cycles in the United States and 50 in Europe) is preferable for electric lighting, as the light is steadier. The higher frequency is also preferable where many transformers are used, as these are cheaper and more efficient at the higher frequencies.

PHASE AND LINE VOLTAGES AND CURRENTS. For moderate voltages, up to 3000 between lines, the method of connection is decided by such details as which

will give a convenient number for the conductors per slot for the required voltage, but for higher voltages the Y connection is usually chosen as it causes a lesser strain on the machine insulation for a given voltage between lines. See also Art. 7.

Single Phase. In a single-phase generator the voltage per phase is the same as the voltage between lines, and the current per phase is the same as the current per line, the product of voltage and current giving the volt-ampere rating of the machine.

Two Phase or Quarter Phase. In a properly designed machine of this type each phase supplies half the rating, thus the voltage and current per phase in the machine are respectively the same as the voltage and current per phase on the line. The current is equal to 1000 × (kva) ÷ 2 × volts per phase.

Three Phase. Machines of this type may be connected either Y or Δ. In a Y-connected machine the current per phase is the same as the current in each line and is equal to 1000 × (kva) ÷ $\sqrt{3}$ × (volts between lines), while the voltage per phase is (volts between lines) ÷ $\sqrt{3}$.

In a Δ-connected machine the line current is equal to 1000 × (kva) ÷ $\sqrt{3}$ × (volts between lines), and the current per phase is equal to (line current) ÷ $\sqrt{3}$, while the voltage per phase is equal to the voltage between lines.

2. DESIGN OF SALIENT-POLE GENERATORS

The procedure in designing an a-c generator for a given power output, voltage, and frequency to fulfil given requirements regarding regulation, efficiency, etc., is partly analytical and partly empirical. The data of five specific designs are given in the section on Examples of Design and Performance, Art. 7. The method of procedure is to lay out a preliminary design from rough calculations, calculate the performance of this design, modify the preliminary design where this calculation indicates, recalculate the performances, etc., until a design is arrived at which meets the given requirements.

DEFINITIONS. The following terminology is used in the discussion of the design of generators:

Pole Arc. The arc subtended by one pole face, measured along the periphery of the armature; in the following discussion it will be expressed in inches.

Pole Pitch. The arc measured along the periphery of the armature from the center of one field pole (N-pole, say) to the center of the next field pole (S-pole); in the following discussion it will be expressed in inches.

Ampere-conductors per Inch of Armature Periphery. The product of the number of conductors per inch measured along the periphery of the armature by the effective amperes flowing in each conductor.

Slot Pitch. The distance in inches measured along the armature periphery between the centers of two adjacent slots. The slot pitch is equal to the pole pitch divided by the number of slots per pole.

Coil Pitch. The number of slots spanned by a coil; that is, if a coil has one side in slot 1, and the other side in slot 7, the pitch of the coil is 7 − 1 = 6. A coil which spans a distance exactly equal to the pole pitch is said to have a "full pitch," but if it spans a lesser distance it is said to have a "fractional pitch." For example, if there are six slots per pole and a coil has one side in slot 1, and the other side in slot 5, it is said to have a fractional pitch of $^4/_6$ or $^2/_3$.

Leakage Factor. The ratio of the flux per pole which enters the armature core to the total flux (including the leakage flux) which would be produced by the field winding. See page 9–09.

PRELIMINARY CALCULATION OF MAIN DIMENSIONS. Let

P_0 = output in kilovolt-amperes (kva).
ρ = ratio; pole arc divided by pole pitch.
B = average magnetic flux density per square inch in air gap.
σ = ampere-conductors per inch of periphery.
V = peripheral velocity in feet per minute at gap.
D = diameter of armature in inches.
L = length of armature along shaft in inches.
N = revolutions per minute.
p = number of poles.
f = frequency in cycles per second.

Then the following relation holds for either a single-phase or a polyphase machine, other than turbo-alternators:

$$P_0 = \frac{\rho\sigma BVDLk_2 k_3}{144 \times 10^9} \qquad (1)$$

Five of the six design constants in the right-hand member of this equation are subject to choice; the equation then fixes the sixth constant. The choice of the values of the various constants should be based upon modern practice, an idea of which is given below in the following paragraphs. For values of the constants k_2 and k_3 see the section below on Predetermination of Performance.

For turbo-generators see section below on Design of Turbo-alternators.

Ratio of Pole Arc to Pole Pitch (ρ) is governed by two antagonistic phenomena; for the sake of small magnetic leakage and good form factor of emf wave a low value is desired; for the sake of low reluctance to the main flux and economy of material a high value is desired. The usual values are ranged from 0.6 to 0.7.

Magnetic Flux Density (B) in the air gap is limited by the exciting ampere-turns required to produce it, length of gap, and sometimes by the heating resulting from core loss. Usual values B are given in the accompanying table.

Cycles	Lines per Sq In
25	44,000 to 58,000
60	36,000 to 50,000

Ampere-conductors per Inch of Periphery (σ) is limited by the heating resulting from high current densities. If ventilation is good, insulation thin, or the slots very deep, as in armatures of large diameters, the values of σ may be high. Usual values of σ for continuous rating and for a rise in temperature of 50 deg cent are:

Ampere-conductors per Inch of Periphery

Diameter of Armature, in.	Less Than 2000 Volts	2000–7000 Volts
0–30	300– 400	....
30–100	400– 600	....
100–200	800–1200	600–1000
200 and up	....	800–1200

With special provisions for ventilation σ may be much greater, as, for example, in turbo-generators (q.v.).

The Peripheral Velocity (V) is determined by the mechanical design. Values run up to 6000 ft per min with no special features of mechanical design, from 6000 to 10,000 in salient-pole machines with special features, from 20,000 to 30,000 in turbo-generators with solid cylindrical rotors of high-grade steel.

The Diameter of Armature depends upon the peripheral speed and the revolutions per minute of the revolving part (N):

$$D = \frac{12\,V}{\pi N}\ \text{inches}$$

The Length of Armature (L)

$$L = \frac{144\,P_s\,10^9}{p\sigma BVDk_2\,k_3}\ \text{inches}$$

All the quantities on the right-hand side of the equation have been set by the preceding considerations, therefore this equation gives a reasonable value for the length.

Number of Poles (P) **and Revolutions per Minute** (N). This is determined by the frequency:

$$p = \frac{120\,f}{N}$$

Flux per Pole

$$(\Phi) = \frac{\pi\,DLB}{p}\ \text{maxwells}$$

Number of Turns in series per phase (S)

$$S = \frac{E\,10^8}{4.44\,f\,\Phi k_2\,k_3}$$

where E = voltage per phase.

This gives a complete, but preliminary and approximate, idea of the proportions of a machine for a given specification.

ARMATURE WINDINGS. Although there are many forms of armature windings which may be used, there are practically only two forms in general use in this country. These are the " chain winding " and the " lap winding."

Chain Winding (Fig. 1). This winding is characterized by having a number of coils equal to half the number of slots; that is, there is only one side of a coil in each slot. The coils may be either form wound and insulated, in which case slots with open faces are

required; or they may be wound by hand in place, in which case partly or entirely closed slots may be used.

There are at least two kinds of coils in each machine. These are characterized by the shape of their end connections, as these end connections lie some in one plane and some in another. If there is more than one slot per pole per phase, there must be four different shapes of coils, having two different pitches; the coils of any one phase per pole are placed concentrically. The chain winding is used in the older small high-voltage machines, 2000 volts or higher.

Lap Winding (Fig. 2). This winding contains a much larger number of coils, all of the same form and size. There may be two, four, six, etc., sides of coils in each slot,

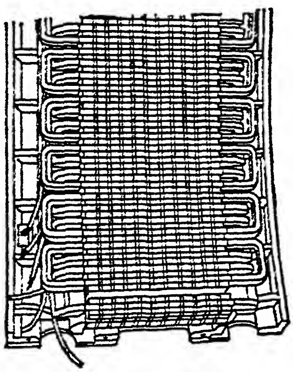

Fig. 1. Chain Winding

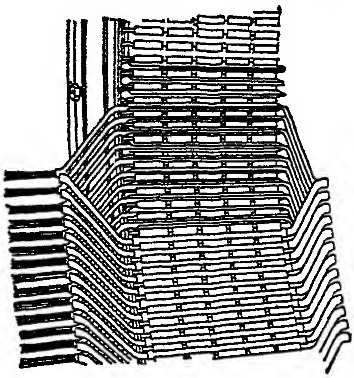

Fig. 2. Lap Winding

the coils being placed side by side two coils deep. This winding is similar to the multiple-drum winding of a d-c armature. With two coil sides per slot the slots must be open, but with more than two coil sides per slot the slots may be partly closed. This type of winding is very convenient if there are a large number of slots per pole.

The coils are connected in groups of two, three, etc., per pole per phase, depending upon the slots per pole per phase. Successive groups or poles of the same phase are connected in series or multiple by "pole connections."

In both forms of winding each coil may contain from one to many turns in series.

NUMBER OF SLOTS. The number of slots per pole on most polyphase machines is usually a multiple of the number of phases as three, six, etc., and this gives a simple winding, but more recently the practice has been introduced of making the number of slots per pole prime to the number of phases in order to provide a better wave shape.

The total number of slots on the armature must be a multiple of the number of phases in order to have equal voltages in the different phases. An example would be a three-phase, four-pole machine with a total of 42 slots or 10.5 per pole but 14 slots in each of the three phases. These would be connected with 14 coils in series in each phase in accordance with the following table:

Phase	Coils per Phase			Coils per Pole
	I	II	III	
Under pole 1...........	4	3	3	10
Under pole 2...........	3	4	4	11
Under pole 3...........	3	3	4	10
Under pole 4...........	4	4	3	11
Total..............	14	14	14	42

All the coils of each phase should be connected in series because the voltages of the separate groups differ both in magnitude and phase. But this winding for these four poles may be connected either in series or in multiple with the winding of another four poles in an eight- or twelve-pole machine (see accompanying table).

Size of Conductors and Slots. The size of each conductor is a compromise between a size which will give a reasonable current density in the conductor, and a size which will properly fill a reasonable slot (see discussion of magnetic circuit below). The current density in the copper conductor is from 2500 amp per sq in. in small machines to 2000 in medium and moderate voltage and 1600 in high-voltage machines.

The conductors are arranged in the slots so that the slots are usually about four times

as deep as they are wide. The size of the slots should be such as to allow a space for insulation over and above the space occupied by the conductors and such cotton covering as they may have. The space required for this extra insulation in straight slots is as follows:

For example, the necessary vertical depth of slot may be found in a machine insulated for 2200 volts with 2 coil sides per slot by multiplying the over-all diameter of cotton-covered wire, or depth of bar, by the number of conductors in a vertical row and adding 0.43 to the produce.

Voltage	Slot Factor	Insulation, in.	
		Vertical	Horizontal
500	0.5	0.350	0.140
2,200	0.42	0.430	0.180
4,400	0.38	0.75	0.250
6,600	0.35	1.00	0.32
13,000	0.30	1.50	0.55

Slot Factor. The ratio of cross-section of copper in a slot to cross-section of slot is known as the slot factor. Normal values of the slot factor for a 1000-kw machine are given in the accompanying table. For smaller machines the slot factor is slightly less and for larger machines slightly greater.

FIELD WINDING. The field winding is usually not calculated until a design of the armature and magnetic circuit has been adopted which will give the required regulation (see Art. 3). The field winding is designed for that value of excitation, ampere-turns per pole, which corresponds to that specified output which demands the most of the field, for instance, the highest value of kva output at the lowest power factor. The usual severe condition is to require rated kva output at an inductive power factor of 80 per cent. An anti-inductive load relieves the field of some of its duty. The correct cross-section of field conductor is definitely set by the relation:

$$q = \frac{0.01\,(\text{mlt})\,Fp}{12{,}000\,E_x} \quad \text{square inches}$$

mlt = mean length of a turn in the field coils, inches.
F = the specified excitation in ampere-turns.
p = the number of poles.
E_x = a specified d-c voltage on the field circuit.

The mean length of a field turn can be estimated from the dimensions of the magnet core. The value of F is determined as in preceding paragraphs. The value of E_x is usually conservatively assigned such as that the machine shall be capable of giving rated kva at 80 per cent power factor with 80 per cent of the rated exciter voltage. The number of field turns per pole is determined by the amount of power (watts) that can be dissipated by the surface of the coils or that it is desirable to dissipate from the point of view of efficiency. The more turns used, the less power is wasted at the assigned voltage. The lower limit of power or upper limit of turns is usually set by space limitations.

$$t = \frac{E_x F}{w}$$

where t = field turns per pole and w = allowable watts in the field, all poles.

The actual resistance of the field winding at 75 deg cent is:

$$R_f = \frac{0.01\,(\text{mlt})\,t\,p}{12{,}000\,q} \quad \text{ohms}$$

The actual excitation loss (not including that in the field rheostat) is $I_f^2 R_f$, in which I_f is the field current for a specified load, $I_f = F/t$. The heating of the field coils is determined by the outer cylindrical surface of the coils: $A = 2c(f + b + 4d)$ (see Fig. 3),

	Peripheral Speed, ft per min	Temp. Rise, °C per watt per sq in.
Revolving Field	1,000	55
	2,500	40
	5,000	25
	10,000	15
Revolving Armature	1,000	80
	2,500	60
	5,000	45
	10,000	30

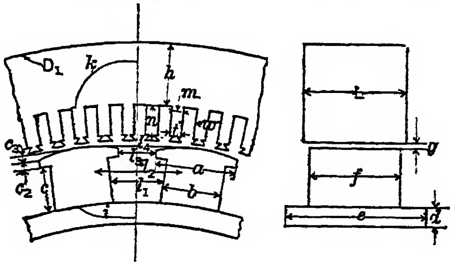

FIG. 3. Dimensions of Magnetic Circuit

and d is the depth of winding in a field coil. The watts per square inch of surface is given by $\frac{I_f^2 R_f}{p A}$.

Temperature Rise of Field Winding. The rise in temperature per watt radiated per square inch of surface of a field coil depends on the peripheral speed of the revolving field or revolving armature. The accompanying table gives the temperature rise in degrees centigrade per watt radiated per square inch. For other rates of radiation the temperature rise is proportional.

3. PREDETERMINATION OF PERFORMANCE OF SALIENT-POLE GENERATORS

The calculations for a quarter-phase or a three-phase machine are very similar and are given together in the paragraphs immediately following. The special features of a single-phase machine are described below. Examples of specific designs and the tested performance are also given below.

Magnetization Curve. The first step is the calculation of the magnetization curve, i.e., a curve showing the relation between the voltage per phase at no load (at normal speed) and the field ampere-turns. To do this the useful flux per pole corresponding to any given value of the no-load voltage is first calculated, and then the field ampere-turns per pole required to produce this flux are determined. A sufficient number of points to give a magnetization curve up to 20 per cent above rated voltage should be calculated.

Useful Flux (i.e., the flux cut by the armature conductors). Let

E = a given value of the terminal voltage per phase with zero armature current.
f = frequency in cycles per second.
S = number of turns in series per phase.
k_1 = a constant, depending on the shape of the pole shoe, which may be called the "pole shoe constant."
k_2 = a constant, depending on the distribution of the armature winding, which may be called the "winding-distribution constant."
k_3 = a constant, depending on the pitch of the armature coils, which may be called the "pitch constant."

Then the useful flux per pole entering the armature is

$$\phi = \frac{E \times 10^8}{4.44\, k_1\, k_2\, k_3\, f S} \tag{2}$$

Pole Shoe Constant (k_1). This constant is proportional to the form factor of the flux distribution around the periphery of the armature. In all modern machines the pole faces are so shaped that this distribution is practically a sine wave, and therefore $k_1 = 1$. This is usually done by making the air gap at the pole tips greater than at the center of the pole.

One method of doing this is to make the outline of the pole face a portion of a circle of such a radius (less than the radius of the armature in revolving field machines) that the gap at the tips is twice the gap at the center.

For very accurate predeterminations the distribution of the flux is carefully calculated. (See S. P. Thompson, Dynamo Electric Machinery, Vol. II, p. 206; C. A. Adams, *Trans. A.I.E.E.*, Vol. 33.)

Winding Distribution Constant (k_2). This constant allows for the fact that if there is more than one slot per pole per phase, the conductors in the various slots of one phase under a pole do not generate emf's of exactly the same phase. Since the slots pass under the pole consecutively the emf's of the conductors reach a maximum consecutively. These emf's must therefore be combined vectorially and not merely added together. k_2 is different in single-phase, two-phase, and three-phase machines.

Slots per Pole	Value of k_2		
	1 phase	2 phase	3 phase
1	1.000	.....	.....
2	0.707	1.000	.....
3	0.666	.....	1.000
4	0.65	0.925	.....
6	0.64	0.912	0.966
8	0.64	0.905	.....
9	0.64	.....	.....
12	0.64	0.90	0.960
18	0.64	0.90	0.960
24	0.635	0.90	0.958
∞	0.632	0.90	0.958

The table at the left gives the values of k_2 for uniformly distributed windings with equally spaced slots.

These constants apply to a winding uniformly distributed around the armature periphery. This is always the condition in a two- or three-phase machine. A single-

phase machine usually has its working winding irregularly distributed so the above constants are only of theoretical interest. (See special treatment of single-phase machines below.)

Pitch Constant (k_3). It is sometimes desirable to use coils having a fractional pitch particularly in machines of large pole pitch, in order to save copper and I^2R loss, and also in any machine to give a particularly good wave shape. When this is done each turn connects in series two conductors generating emf's which are not in phase and their resultant is therefore not as great as their arithmetic sum. The constant k_3 is the ratio of this resultant or vector sum to the arithmetic sum of the two emf's. The relation between k_3 and winding pitch expressed as a percentage of the pole pitch is given in the accompanying table.

Per Cent Pitch	k_3
100	1.00
83	0.97
80	0.95
75	0.93
67	0.87
50	0.71

Leakage Factor (ν). The leakage factor, i.e., the ratio of the total flux produced by the field to the flux which enters the armature, may be determined by calculating the permeance of the path of the armature flux and the permeance of the various leakage paths. The sum of the permeances of the main and leakage paths, divided by the permeance of the main path, is then the value of ν.

Referring to Fig. 3, the average radial depth of the air gap is approximately $1.25\,g$, and the reluctance of the gap is therefore $1.25\,g/af$. The reluctance to the useful flux of the iron part of the magnetic circuit is about 20 per cent of that of the gap in 60-cycle machines, and 40 per cent in 25-cycle machines. Hence the approximate value of the permeance of the path of the main flux is

$$P_0 = \frac{af}{1.5\,g} \text{ for 60 cycles} \quad \text{and} \quad P_0 = \frac{af}{1.75\,g} \text{ for 25 cycles.}$$

The flux emanating from or entering each side of a pole has a path l_1 inches long and cf square inches in cross-section. The permeance of this path to the plane midway between a pair of poles is $2\,cf/l_1$. There are two of these paths in multiple, one in each direction, from opposite sides of each pole. The total permeance of this path per pole is therefore $4\,cf/l_1$. If a uniform mmf acted on this path at all points the flux would be proportional to this permeance, but since the mmf varies from 0 at the yoke to the full mmf per pole at the pole shoe, the average mmf is one-half the mmf per pole. The leakage flux through this path is therefore proportional to the mmf per pole and to one-half this permeance. Hence the "effective permeance" of this path is

$$P_1 = \frac{2\,cf}{l_1}$$

The same reasoning applies to the flux which leaks out from the end surface bc (see Fig. 3) of the poles, giving as the effective permeance of this path

$$P_2 = \frac{2\,bc}{l_1 + b/2} = \frac{2\,bc}{l_2}$$

The leakage between the pole tips is due to the total mmf per pole, and the permeance of this path is therefore

$$P_3 = \frac{4\,c_2 f}{l_3}$$

The leakage from the faces of the poles at the chamfer is also due to the total mmf, and the permeance of this path is

$$P_4 = \frac{4\,c_3 f}{l_4}$$

The leakage factor is then

$$\nu = 1 + \frac{P_1 + P_2 + P_3 + P_4}{P_0} \tag{3}$$

Usual Leakage Coefficients

Salient-pole Machines

Pole Pitch, in.	Leakage Coefficient
6	1.4
12	1.3
18	1.25
24	1.2
36	1.15
42	1.1

Ampere-turns. The ampere-turns required to produce the useful flux ϕ may be calculated by the following systematized procedure. The symbols are: ϕ = useful flux per pole; ν = leakage factor; l = effective length of armature iron; s = pitch of slots at gap; D = diameter of armature at gap; D_1 = outside diameter of armature iron. Other dimensions as shown in Fig. 3. All dimensions are in inches.

Part	Flux	Cross-section, A	Flux Density = flux, A	Ampere-turns per Inch, m *	Length of path, λ	Total Ampere-turns $= m\lambda$
Field yoke	$0.5\ v\phi$	dc	......	......	i	......
Field pole	$v\phi$	$0.95bf$	......	......	c	......
Air gap	ϕ	af	......	......	See below	......
Armature teeth	ϕ	See below	......	......	n	......
Armature core	$0.5\ \phi$	hl	......	......	k	......

* The value of m is found from the B–H curves in the article on Magnetic Properties when the flux density has been calculated.

Usual Magnetic Densities

Part	Density
Air gap, 25 cycles	44,000 to 58,000
60 cycles	36,000 to 50,000
Armature teeth	90,000 to 100,000
Armature core	50,000 to 70,000
Field pole	90,000 to 100,000
Field yoke	70,000 to 80,000

Field Yoke. The field yoke carries only half as much flux as the pole piece, as the flux divides at this point. The material is usually cast or forged steel. Find the magnetic density as indicated, and refer to the proper magnetization curve to find the ampere-turns magnetizing force per inch for this density. The length of path is one-half the distance from the center of one pole to the center of the adjacent pole and is shown by i in Fig. 3. Find the total ampere-turns as indicated.

Field Pole or Magnet Core. This carries all the flux. The material is usually sheet steel of high permeability, but sometimes solid steel (formerly). The factor 0.95 is used for laminated steel poles; for solid poles this factor is of course unity. The length of this path is usually taken as c, the length of the space for the field spool. This is not strictly accurate, but the density in the pole shoe (c_1) is so low that the excitation required for this part is negligible.

Air Gap. Not all the flux in the pole piece crosses the gap, as some leaks across the interpolar space. The value of the flux in the gap is the same as the useful flux in the armature. For the area of gap section the cross-section (af) of the pole shoe is taken. The length of the path in the air gap is taken as the mean of the gap length. As the maximum length (at the pole tips) is usually made twice the minimum, and the outline of the pole face is made the arc of a circle, the average length is usually 1.25 times the minimum. The ampere-turns per inch are 0.313 × (density per square inch).

The minimum clearance between armature core and field poles in modern generators is given in the accompanying table.

Armature Diameter, in.	Minimum Air Gap, in.
40	0.15
80	0.20
120	0.30
160	0.40
200	0.50
240	0.60

Armature Teeth. The flux is confined at any one time to a certain portion of the teeth per pole known as "teeth under one pole." Since the flux spreads somewhat on leaving the pole piece it is logical to assume that it takes up a peripheral length equal to the pole arc plus twice the length of the air gap. If, therefore, this length is divided by the pitch of teeth at the periphery of the armature, the quotient is the average number of teeth carrying flux at any given instant. This figure may quite properly contain a *fractional* number of teeth. The teeth being wedge shaped or sectors of a circle, that cross-section (not the mean cross-section) which will give the average excitation must be chosen, since saturation increases more rapidly than the cross-section decreases. A good approximate value is found at a point one-third the distance from the minimum width towards the maximum width.

The effective cross-section of the teeth is then equal to this width multiplied by the product of the effective length of the core by the number of the " teeth under one pole." The effective length of core is the net length of iron in the core after deducting the space occupied by air ducts and insulation between sheets of steel. This latter is usually 5 per cent of the measurable length of iron. The effective length (l) = 0.95 × (total length of armature core less space occupied by ducts).

Armature Core. The flux divides again in the armature core, one-half the useful flux being in each section of the armature core. The core is made of annealed sheet punchings. The cross-section of core is equal to the radial depth of core back of the

slots multiplied by the effective length of iron in the core. The length of path is a little greater than one-half the pitch of poles at this radius, and is as shown at (*k*), Fig. 3.

Open-circuit Saturation Curve. A number of points, for various voltages from 50 up to 120 per cent of rated voltage, are calculated as above and a curve is plotted with volts per phase as ordinates and mmf in ampere-turns per pole as abscissas. This is the designer's curve. For commercial purposes the scales are volts between terminals and field current in amperes. The latter is obtained as on page 9–07.

ARMATURE RESISTANCE AND COPPER LOSS. The length of wire in one phase of the armature winding is calculated from the mean length of a turn and a number (S) of turns in series per phase. A turn consists of two straight portions imbedded in the slots, and the end connections at the two ends. A fairly accurate empirical method of figuring this is:

$$(\text{m.l.t.}) = 2L + \frac{10\,D_w\,k_w}{\text{poles}}\ \text{inches}$$

where L = total length of armature core.
D_w = pitch diameter of the winding along a circle at the center of the slots, i.e., diameter of the armature at the face plus the depth of a slot.
k_w = fractional pitch constant, i.e., coil pitch divided by the pole pitch.

Let $q \equiv$ the cross-section of one conductor (square inches) and $m \equiv$ the number of these conductors in parallel in one phase; then the resistance per phase of the armature at 75 deg cent is:

$$r = \frac{0.01\,S(\text{m.l.t})}{12{,}000\,q\,m}\ \text{ohms}$$

(0.01 is the resistance of a copper conductor of 1 sq in. cross-section and 1000 ft length at 75 deg cent.)

In a Y-connected armature the resistance between terminals is twice the resistance per phase, and in a delta connection it is two-thirds the resistance per phase. The total copper loss in the armature at I amperes per phase is $3\,I^2 r$ in a three-phase winding and $2\,I^2 r$ in a two-phase winding. Usual values are given in the table on page 9–14. The percentage Ir or resistance drop is $\frac{100\,Ir}{E}$. For reasonable heating the $I^2 r$ loss in each coil at rated load should be between 0.25 and 0.40 watt per square inch of actual outside surface of the coil itself. Surface = $(u + 2w) \times$ (m.l.t.). See Fig. 4.

ARMATURE LEAKAGE REACTANCE. The load current in flowing through the armature conductors sets up a local magnetic flux which interlinks with the conductors, thus producing inductance. The inductance, L, of any circuit is:

$$L = 3.2\,S^2\,P \times 10^{-8}\ \text{henrys}$$

where S = number of turns in series and P = permeance of the flux path in inches.

The corresponding reactance is $x = 2\,\pi f L$, where f is the frequency. This reactance causes a loss of voltage and a "dephasing" effect or lag of current behind the emf.

There are several parallel paths for this armature leakage flux, each path surrounding one or more conductors or slots.

1. That crossing the slot and passing through the windings. Here each line of flux interlinks a different number of conductors, and the average interlinkages must be calculated.

2. That crossing the upper part of the slot above the windings. All this interlinks all the conductors in one slot.

In the case of slots with full openings as usually employed in generators the effective permeance or equivalent flux per ampere-conductor for these two paths is (see Fig. 4):

$$P_s = 3.2\,L\left(\frac{u}{3w} + \frac{p}{w}\right)$$

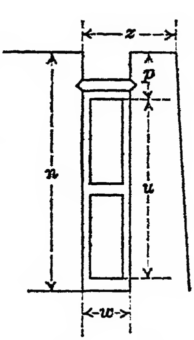

Fig. 4. Stator Slot Dimensions

3. That passing along the air gap from tooth-tip to tooth-tip. This is known as the "belt leakage" as it is caused by the combined mmf of the several slots in one phase belt.

$$P_t = \left(2.35\log_{10}\frac{\pi z}{2w} + A\right)L$$

where A is a constant depending upon s_1, the slots per pole per phase, as follows:

s_1.......	1	2	3	4	5	6	7	8	9	12	15	18
A.......	0	0.35	0.70	1.1	1.6	2.1	2.7	3.2	3.8	5.4	7.1	8.8

4. That surrounding a group of end connections of the coils per pole per phase and interlinking all the coils of this group. This is known as the "end connection leakage."

$$P_c = 0.58\, s_1\, l_c \log_{10} \frac{2l_c}{U_c}$$

for a double layer winding,

where l_c = length of end connections at one end = $1/2$ (mean length of a turn) $- L$.

$U_c = u + 2\, s_1 w$ = the perimeter of a coil.

Let the total permeance of the flux path around the group of conductors forming one side of a coil be $P = P_s + P_t + P_c$; then the reactance in ohms per phase is:

$$X = 2\,\pi f p s_1\, c^2\, k_2\, k_3\, P\, 10^{-8}$$

where p = number of poles.

c = effective conductors per slot $= \dfrac{\text{conductors per slot}}{\text{paths in parallel}}$.

f = frequency.

k_2 and k_3 = winding and pitch factors as on page 9–08.

s_1 = slots per pole per phase.

The reactance drop in volts is IX, where I is the current per phase. For purposes of comparison the "percentage reactance drop" is more significant. This is $100 \dfrac{IX}{E}$. It ranges between 10 and 20 per cent for 60-cycle generators and between 8 and 15 per cent for 25-cycle machines.

ARMATURE REACTION. When current flows through the armature the armature winding becomes the seat of a mmf which reacts on the field mmf and either distorts or diminishes the useful flux. If the current in the armature is in phase with the generated emf it causes a "cross magnetizing" force acting along an axis passing midway between any pair of poles.

As the phase of the current in the armature changes, the direction of the magnetizing force due to the armature mmf shifts, and a component is introduced either opposed to the field magnetizing force (for lagging current) or assisting the field magnetizing force (for leading current). In a polyphase generator the magnetizing force due to the armature mmf for a given armature current is constant in magnitude and has a fixed direction with respect to the field magnetizing force, depending on the phase of the current.

If the field iron had no polar projections or intepolar spaces, the direction of the armature magnetizing force would be such that the angle between this magnetizing force and a line perpendicular to the field magnetizing force would be equal to the phase angle between the induced voltage and current.

With the usual type of alternator having interpolar spaces the reluctance of the path offered to the armature mmf is intentionally much greater than that offered to the field mmf. The result of this is that the effect of armature reaction is minimized. The non-uniformity of the field iron, however, changes the relative directions of the two magnetizing forces and renders accurate calculations difficult. As a rule, however, the approximation resulting from the assumption of uniform distribution of field iron is sufficiently accurate. The error introduced by this assumption is on the safe side, since the armature reaction as thus calculated is greater than its actual value.

Armature Reaction Ampere-turns per Pole. Let S = number of turns in series per phase; I = effective value of armature current per phase; p = number of poles, and k_3 = pitch constant of the winding (see above under Magnetization Curve). Then the armature ampere turns per pole effective in producing armature reaction are

$$\frac{\sqrt{2}\, k_2\, k_3\, SI}{p} \quad \text{for two-phase machine}$$

$$\frac{1.5\,\sqrt{2}\, k_2\, k_3\, SI}{p} \quad \text{for three-phase machine}$$

As noted above, the armature reaction for a given effective value of the current is constant in magnitude. The armature reaction in single-phase generators is given in the discussion of these machines below.

The armature reaction ampere-turns of different machines at full rated load is greater for a high than for a low pole pitch, and is less for high frequencies than for low frequencies. The permissible armature reaction ampere-turns depend, of course, upon the desired regulation.

A reasonable value for armature reaction would be between 1500 and 5000 amp-turns per pole for a 25-cycle machine and between 1000 and 4000 for a 60-cycle machine.

SYNCHRONOUS REACTANCE. The effect of the armature leakage reactance and armature reaction upon the terminal voltage of a generator at given field excitation are of like character, since the voltage induced in the armature due to each of these causes is in quadrature with the current. The "synchronous reactance" of a generator is the equivalent reactance which would produce the same effect as the armature leakage reactance and armature reaction combined.

The synchronous reactance may be predetermined by finding the excitation ampere-turns (from magnetization curve) corresponding to a voltage equal to the drop due to leakage reactance and adding to these ampere-turns the armature reaction ampere-turns. The voltage from the magnetization curve corresponding to this sum divided by the armature current per phase gives the synchronous reactance per phase.

REGULATION. The regulation of a generator machine is defined as the ratio of the difference in terminal voltage at no load and at full load to the full-load voltage, the field excitation being kept constant at its full-load value. Expressed as a percentage the regulation is $100(V_0 - V) \div V$, where V is the full-load terminal voltage and V_0 the no-load terminal voltage at full-load field excitation.

Several different methods are employed for calculating the regulation. One known as the "electromotive-force method" uses the synchronous reactance and is very convenient but not very accurate, being pessimistic. It is used for qualitative methods and for predicting the curves of the general characteristics. The second is the "magnetomotive-force method," which employs the open-circuit saturation curve and the armature reaction and, though more accurate than the first method, is optimistic. It is the most rational and readily understood. The third method is the official method of the A.I.E.E. Standards (which see).

Electromotive-force Method. Let V = terminal voltage per phase at full load; R = a-c or effective resistance per phase in ohms; XI = volts per phase from magnetization curve corresponding to the field excitation required to send full-load current through armature on synchronous impedance test; I = full-load amperes per phase; $\cos\theta$ = power factor. Then the voltage per phase E at no load, corresponding to the full-load excitation, is the vector sum of V, RI and XI, or

$$E = \sqrt{(V\cos\theta + RI)^2 + (V\sin\theta + XI)^2}$$

The regulation is $100(E - V)/V$, and the full-load field ampere-turns F is taken from the point corresponding to E on the magnetization curve.

Magnetomotive-force Method. One way in which this method has been applied is the following: Let V = terminal voltage per phase at full load; R = a-c resistance per phase in ohms; I = full-load amperes per phase; $\cos\theta$ = power factor of the load; X = leakage reactance per phase in ohms. Calculate

$$V' = \sqrt{(V\cos\theta + RI)^2 + (V\sin\theta + XI)^2} \quad \text{and} \quad \theta' = \tan^{-1}\left[\frac{V\sin\theta + XI}{V\cos\theta + RI}\right]$$

taking θ' positive for I lagging behind V'. From magnetization curve find m = excitation ampere turns corresponding to V' and let n = armature reaction ampere-turns per pole for current I (see page 9–12). The total field ampere-turns is then

$$F = \sqrt{m^2 + n^2 + 2\,mn\sin\theta'}$$

Let V_0 = voltage per phase from the magnetization curve corresponding to this excitation F; then the regulation is

$$100\,\frac{V_0 - V}{V}$$

LOSSES. The losses in a synchronous alternating-current generator or motor are

(a) Friction, bearing and windage.
(b) Excitation or field copper loss.
(c) Core loss.
(d) Armature copper loss.
(e) Load loss.

Of these the first three are approximately constant for various loads, but the last two vary as the square of the load current.

Friction and Windage depend in magnitude upon the details of the physical or mechanical construction, the amount of induced ventilation, and speed. It is impossible to give a method of predetermining this quantity which will apply to various designs and makes. Each manufacturer has an empirical formula for each line of machines. This loss ranges from 2.5 per cent in 100-kva machines to 0.5 per cent in 10,000-kva machines. These values are for complete machines with their own bearings (two in number). Some machines are designed with only one bearing, the other bearing being a part of the prime

mover (hydraulic or steam) in which case the friction chargeable to the generator is less. Some machines with devices to produce ventilation, such as fan blades attached to the revolving part, have greater friction losses.

Core Loss. The core loss is made up of hysteresis and eddy-current losses. These losses are principally in the armature core and teeth, but if proper care is not taken there may be a considerable loss in the frame of the machine and the pole shoes.

It is a simple matter to calculate the magnitude of these losses in the armature core proper, as the frequency and flux density are definite in this part, but the losses in the teeth are due not only to the fundamental frequency and main flux, but also to pulsations due to the passage of pole tips past the teeth and the leakage flux of the armature. The total core loss is the sum of the hysteresis and eddy-current losses. See Magnetic Properties of Iron and Other Metals for curves of hysteresis and eddy-current losses and formulas for their calculation.

Excitation Loss. The calculation of the field current and of the resistance of the field winding is given above in the section on Field Winding. The total power required for excitation will be the product of this resistance and the square of the current.

If the machine is separately excited, which is usually the case, the losses in the field rheostat are, by convention of the A.I.E.E., not chargeable against the generator.

Armature Copper Loss. The calculation of the d-c resistance per phase of the armature winding is given above in the paragraph on Armature Resistance (page 9–11). The total armature copper loss is equal to the number of phases times this d-c resistance times the square of the current per phase.

Load Loss. When a current flows in the armature conductors a local flux is set up which will cause eddy currents in these conductors, if they are not well subdivided, and in the surrounding iron, as well as a hysteresis loss in the surrounding iron. The loss due to this load flux is called the "load loss."

The load loss is a function of the leakage flux and the subdivision of the conductors. A large number of turns of fine wire will involve a very small loss. If the conductors must be large, they may be made of stranded cable pressed to shape. It is almost impossible to calculate this loss, and very difficult to measure it. A rough method is to assume the resistance per phase increased by 15 to 25 per cent, as this loss, like the true copper loss, is proportional to the square of the armature current. The total amount of the loss is less than 1 per cent of the input in well-constructed machines.

EFFICIENCY. Let P = total output in kilowatts; R_a = resistance per phase of armature; I_a = armature amperes per phase; R_f = resistance of field winding; I_f = field current; q = number of phases; C = total core loss in kilowatts; and F = friction and windage loss in kilowatts. Then the per cent efficiency is

$$\frac{100\,P}{P + C + F + (1.15\,R_a qI_a^2 + R_f I_f^2) \times 10^{-3}}$$

This assumes the load loss equivalent to increasing the armature resistance (as calculated or measured by direct current) by 15 per cent. If the load loss is determined from the short-circuit core loss the formula for efficiency is

$$\frac{100\,P}{P + C + F + L + (R_a qI_a^2 + R_f I_f^2) \times 10^{-3}}$$

where L is the load loss in kilowatts for the specified current I_a.

The efficiency is a maximum for that load at which the constant losses are equal to the variable losses.

Customary values for the efficiency at full load and each of the losses at full load for various sizes of generators are given in the following table. These values are merely indications and vary with the frequency, voltage, speed, power factor, etc. A 60-cycle

Efficiency and Losses, Usual Values

Salient-pole Machines

Rating, kva	Efficiency, per cent	Friction, per cent	Excitation, per cent	Core, per cent	Armature,* per cent
100	91	2.5	2.5	2.4	1.6
500	94	1.1	1.5	2.2	1.2
1,000	95	0.9	1.0	2.1	1.0
2,000	96	0.6	0.7	1.8	0.9
3,000	96.5	0.6	0.6	1.7	0.8
5,000	97	0.55	0.4	1.6	0.5
10,000	97.2	0.5	0.35	1.5	0.45

* Copper and load loss.

low-voltage machine will be likely to have a better efficiency than a machine of the same rating for 25 cycles or high voltage.

HEATING. The rise in temperature of the field windings is as given on page 9–07. The rise in temperature of the armature winding and the core is determined by the method given for Heating under Direct-current Generators, page 8–19. Armatures of a-c machines are usually stationary and exterior to the revolving field structure; the armatures of d-c machines always revolve and are inside the field structure. Nevertheless, the design of the ventilation is the same in both cases. The air set in motion by the peripheral velocity of the field poles, and in some cases fan-blades on the poles, enters the radial air ducts in the armature structure, passes the coils where they cross the air ducts, and then cools the iron of the stator core. At the two ends the air from the revolving field fans the end connections, which have spaces between them for the purpose, and thus cools this portion of each coil. The velocity of this air can only be estimated, and the peripheral velocity of the external surface of the field poles is used as a criterion in the formulas for rise in temperature at the surface of coils and core. The armature or stator has air ducts every 2 or 2.5 in., and these are $^3/_8$ or $^1/_2$ in. wide and so arranged that the air flows radially outward from the air gap to the outside frame.

CHECKING CALCULATIONS. Substitution in the following formula gives an excellent check on the above calculations:

$$\frac{DL_f}{Q} = \frac{KA \times 10^9}{fB_g\,na}$$

where D = diameter of rotor at gap in inches.
L_f = length of pole face parallel to shaft.
Q = total kva of generator.
f = frequency in cycles per second.
n = armature reaction ampere-turns.
a = pole arc in inches.
A = diameter per pole in inches.
B_g = flux density, lines per square inch in air gap.
K = 22.5 for single-phase and 15.9 for two-phase or three-phase generators.

4. SINGLE-PHASE GENERATOR

Single-phase generators do not make as effective use of material as do polyphase generators, for the reason that the armature winding can occupy effectively only about one-half of the peripheral surface of the armature; if it occupies more than this there will be voltages generated in the windings which are so out of phase with each other that the resultant voltage is only from 63 to 70 per cent of the sum of all the voltages generated.

Therefore, if a polyphase generator is used as a single-phase machine with the same magnetic densities and the same copper densities, the output will be much less on account of the lesser voltage available. It is customary, therefore, to overload the magnetic elements of the machine somewhat to raise the voltage and thus reduce the overload on the copper which would be necessary to get the desired output. However, if both the iron and copper densities are increased until the machine gives as much output single phase as it is intended to give polyphase, there will be an increased heating. Thus, for the same heating, obtained by a readjustment of the iron and copper losses, a machine of a given first cost will give about 75 per cent as much output single phase as may be obtained polyphase.

In addition to the disadvantage of a single-phase generator that it cannot make use of all the periphery of the armature, it also labors under the disadvantage that its armature reaction is pulsating instead of constant, and this introduces an additional loss in the form of eddy currents.

By using two phases in series of a three-phase machine, or one phase of a two-phase machine, a fairly good single-phase machine is obtained. By arranging the winding slightly differently the same number and arrangement of inductors (or coil sides) can be connected up to give a simpler winding requiring no crossings of coils, that is, a winding "in one plane."

The formula for the calculation of the emf of a single-phase generator is

$$E = 4.44\, k_2\, k_3 f S \Phi\, 10^{-8},$$

where the symbols, with the exception of k_2, have the same significance as in the formula for polyphase machines, page 9–05. The value of k_2 depends upon the portion of the armature periphery (including the teeth between slots) occupied by the main winding. Let A = this fraction of the armature surface; then the corresponding values of k_2 are

given in the accompanying table. The value of A corresponding to a uniformly distributed winding is unity.

A	k_2
1	0.63
3/4	0.785
2/3	0.83
1/2	0.90
1/3	0.956

The average value of the armature reaction ampere-turns per pole of a single-phase machine is SI/p, where S = the number of turns, I = the armature current per phase, and p = the number of poles, but this quantity pulsates between 0 and twice the above value. The evil effects of this pulsating may be reduced by employing a short-circuited winding having its axis at 90 deg to the main field winding. A squirrel cage or "amortisseur" winding in the pole faces is frequently employed for this purpose.

Owing to this pulsating action the load losses are greater, and this should be taken into account in calculating the efficiency and regulation by considering the effective armature resistance as 1.15 to 1.5 times the d-c resistance.

The leakage reactance of a single-phase machine pulsates between a value equal to that obtained by the formula above in the paragraph on Armature Leakage Reactance, and a value two-thirds as great. Satisfactory results are obtained by multiplying the value obtained from the formula by 0.85 for the effective single-phase value. In this case the whole winding is considered as one phase.

5. DESIGN OF TURBO-GENERATORS

In turbine-driven generators the steam turbine is usually built by the same company that builds the generator, and the two machines are practically one unit. The steam turbine has developed to such an extent that for a given capacity in power it weighs less than a reciprocating engine, occupies much less space, costs less, and is more economical of steam and fuel. Good economy in steam turbines, however, is obtained only with high angular velocities. This has made it difficult to apply the turbine to useful purposes. The electric generator has shown itself to be the most suitable device to absorb the power of the turbine and make it available in subdivided form and at convenient speeds for general application. However, it required many years of experience to develop an electric generator which would operate successfully at the high angular velocities suitable for direct connection to the steam turbine. The principal difficulty was the design of a construction which would withstand the enormous stresses in the revolving member which resulted from the centrifugal force. Thus the design of the machine as a whole is largely a question of the type and construction of the rotor, which is the field.

NORMAL WEIGHTS AND SPEEDS. Most turbo-generators have much more copper on the fields and less on the armature than do slow-speed machines, although the total amount of copper is not far different in the two classes. The turbo-generator has much less magnetic iron on account of its high speed. It is quite normal in machines of 15,000-kva capacity to operate at 3600 rpm and machines of 100,000-kva at 1800 rpm. To do this involves the use of peripheral speeds of from 15,000 to 27,000 ft per min. At these high speeds the amount of material per kilowatt is much reduced. Increasing the speed tenfold reduces the weight of material to about one-quarter. This low weight is somewhat offset by the higher cost of construction necessary to withstand the enormous centrifugal forces. Most of the machines, even the large sizes, have two or four poles, or at most six poles. This involves the use of a pole pitch of 30 to 40 in. in 60-cycle machines, and 60 to 90 in 25-cycle machines. Since such large powers are concentrated in such small bulk, a great deal of energy in the form of losses must be dissipated in a small space. Thus special means of ventilation must be provided, such as numerous air ducts, fan blades on the rotor, or a separate blower, and a supply of clean, cool air.

CONSTRUCTION OF ROTOR. The design of a turbo-generator differs from that of the salient-pole type described above, because the revolving field of the turbo-generator consists of groups of coils placed in slots and distributed concentrically about the pole centers or cores, which resemble large teeth. The center of a pole occupies about one-third of the pole pitch and has no slots; see Fig. 5. The distributed field winding gives a peaked shape to the flux wave in the air gap, which is made to approach a sine form as near as practicable as shown in Fig. 6, which shows a developed cross-section of one pole. Thus the pole arc is the same as the pole pitch, but the maximum flux density is approximately 1.5 times the average.

The air gap is usually very large in order to provide a path for the large volume of ventilating air required. On account of the high peripheral speeds customary the diameter per pole is high.

The centrifugal force in the revolving member is from 1500 to 2500 lb for every pound of material near the periphery. A method for determining the centrifugal force in every

part is given in Electric Machine Design, by Gray, and in High-speed Dynamo-electric Machinery, by Hobart and Ellis.

The rotor must be of substantial and rigid construction, so that the critical speed of vibration is above the normal speed of operation. There are several methods of construction, prominent among which are:

a. A solid steel forging turned to shape with radial slots containing a distributed field winding. The shaft is in one piece with the field core; see Fig. 5.

b. A built-up structure consisting of steel disks about 3 in. thick held between the two end-plates by through-bolts, the radial or parallel slots being milled in the assembled structure.

c. Steel laminations with radial slots, assembled on a forged-steel shaft.

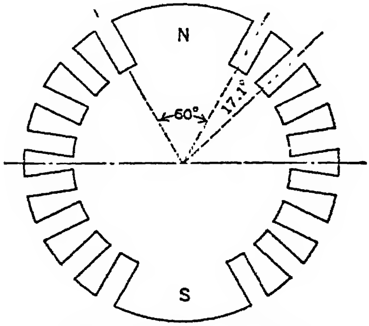

Fig. 5. Rotor Cross-section

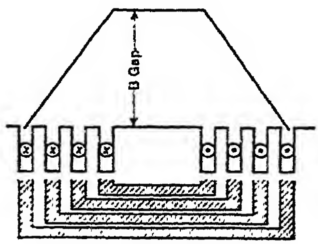

Fig. 6. Field Distribution

In these revolving fields the length is about the same as the diameter, and in large machines the length is greater than the diameter. The air gap is from 1 to 2 in. A uniform air gap is necessary to prevent noise and strains.

CONSTRUCTION OF STATOR. Since the pole pitch is large, a large number of slots per pole is used (12 to 24), and this gives a low armature self-inductance and high short-circuit current. Owing to the long pole pitch the end connections are long and subjected to considerable mechanical forces, as a result of the leakage flux. They must, therefore, be held securely in place by non-magnetic supports. For armature reaction in ampere-turns per pole values of 8000 to 20,000 are common, and the field winding is usually of a capacity of three times the armature ampere-turns. The regulation is poor (20 to 30 per cent). This defect is readily overcome by the use of automatic voltage regulators (see Section 12, Art. 18).

PROVISION FOR VENTILATION. The ventilation of these machines is a problem similar to that of air-blast transformers. Thus there must be provided: (*a*) sufficient

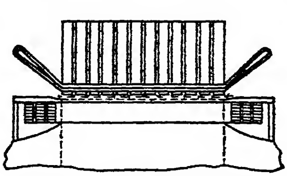

Fig. 7. Radial Ventilation

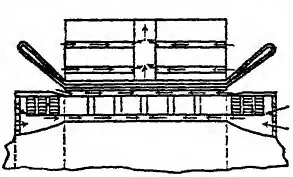

Fig. 8. Axial Ventilation

air to carry off the heat generated with a reasonable rise in temperature of the machine and the air; (*b*) ample duct capacity to prevent too high velocity of the air; (*c*) proper spacing of the ducts so that there is no part very far from an air duct; (*d*) proper precautions to prevent the air from carrying dirt and moisture into the machine.

One hundred cubic feet of air per minute at 20 deg cent will carry off 1 kw with a rise in the temperature of the air of 18 deg cent. Velocities of the air of 5000 to 6000 ft per min are common in the machine proper. The surface cooled will give off 4 or 5 watts per square inch with a rise of 35 to 45 deg cent above the cooling air.

There are two methods of ventilation (Figs. 7 and 8), the "radial" and the "axial." With the increase in size and therefore length of machines the axial becomes less desirable

and less used while the radial system is particularly adapted to long machines because of a refinement known as the multiple radial system (see Fig. 9).

In the simple radial method, air enters the air gap at both ends, flows along the gap, and then branches out radially through the air ducts in the core (3/8 in. wide spaced every 2 in.) at right angles to the shaft and goes to the extreme outer periphery of the stator. In the multiple radial the box frame outside the core is divided into air-tight compartments or large ducts, which are, alternately, for outgoing and incoming air. The middle third of the outside may be surrounded by an incoming duct which sends air radially inward through the core ducts to the air gap. There the stream divides into two parts, moves along the gap, and then radially outward through the two outer thirds of the core length. Air will also enter the air gap at the two ends and flow outward through the air ducts in the core near the ends. There may be any number of these multiple paths, depending upon the length of the core. In the axial method the air enters the air gap at each end and also many small ducts in the core back of the slots and parallel to the shaft. The air flows through these towards a large (3-in.) radial duct at the center of the machine, and then radially outward. The machine is totally enclosed in either case, and the air is propelled either by fan-blades on the rotor or by a separate motor-driven blower. The air is taken in at a definite entrance, usually outside the power house, and is expelled at a definite exit and is frequently used as preheated air for the fires under the boilers.

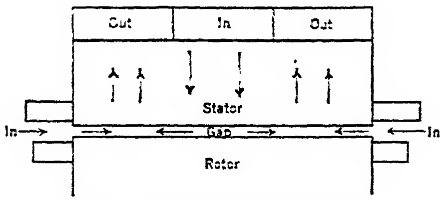

FIG. 9. Multiple Radial Ventilation

SUITABLE SPEED AND NUMBER OF POLES. For 25-cycle machines, 2 poles and 1500 rpm are used for all sizes including 160,000 kva. For 60 cycles, 2 poles and 3600 rpm are used up to 25,000 kva, 4 poles and 1800 rpm up to 200,000 kva. The data of five specific designs are given in Art. 7, page 9–26.

PRELIMINARY CALCULATION OF MAIN DIMENSIONS, Eq. (1), page 9–04, applies, but customary values of some of the constants are quite different for reasons stated above.

p is usually unity with distributed field windings.

B, the average density in air gap varies from 25,000 lines per square inch in 60-cycle machines to 32,000 in 25-cycle machines. Maximum density is 1.5 times the average.

V, the peripheral velocity, varies from 15,000 ft per min in small, low-frequency machines to 27,000 in large machines, figured at the surface of the revolving field.

σ, the ampere conductors of the armature per inch periphery of the field must be figured on the same diameter as V in order for the equation to check. σ has values from 1000 to 1800 (see table, page 9–05).

D = outer diameter of field, in inches, depends upon rpm and peripheral speed.

L = total length of field parallel to shaft, in inches.

k_2 and k_3 the same as on page 9–08.

THE ARMATURE WINDING. This winding is usually a double layer barrel with as many coils as slots and one, two, or three turns per coil. The coils usually have a pitch two-thirds that of a pole in order to shorten the end connections, save copper and space, and reduce the copper loss. It is of the lap winding type shown in Fig. 2. There may be as many circuits in multiple in each phase as there are poles, in order to reduce the amount of current per circuit. Each turn is usually given two twists so that it lies near the top of the slot on one side and near the bottom on the other side.

Connection of armature winding may be single-phase, two-phase, three-phase Y, or three-phase delta. For all three-phase machines for more than 6600 volts, the Y-connection is usually employed, for the reasons given on page 9–04.

General Proportions. The flux per pole depends upon the value chosen for B, the magnetic density in the gap (page 9–05); the required number of turns in series per phase (S) is determined by the volts per phase and the flux (page 9–05). There are usually 12 to 15 slots per pole in a small 60-cycle machine and as many as 24 in a large 25-cycle machine. Each slot contains two coil-sides and has two, four, or some even number of conductors divided in the two coils.

Size of Armature Conductors. A current density of 1500 amp per sq in. is common. On account of the high currents in large machines it is customary to divide the winding into multiple paths, each phase having a multiple path in each pole, thus a four-pole machine may have two or four paths in multiple in each phase. To reduce eddy-current

losses and facilitate bending, the conductors are usually made up of several strands of rectangular wire laid parallel and insulated from each other by cotton covering. This makes it possible to build up a conductor of convenient shape, but necessarily reduces the slot space factor.

Size of Armature Slots. The slot factor is low for machines of this type for three reasons: (1) high voltage is customary, (2) a considerable part of the slot is left vacant to serve as a passage for ventilating air, (3) the winding is placed deep in the slot to give sufficient reactance to limit the instantaneous short-circuit current. A typical slot would be 6 in. deep by 1 in. wide with the winding and wedge occupying only 5 in. of the depth. Usual depths of slots are shown in Table 6; slot factors and space allowed for insulation are given in Table 1. These are explained on page 9–07.

The Useful Flux in Armature is found as given on page 9–08, and has very high values as shown in Table 6. This is because the output per pole is so great. The leakage coefficient runs quite uniformly from 1.1 to 1.15 and is low because of the large pole pitch and distributed field winding.

Table 1. Slot Factor and Slot Insulation

Machine Voltage	Slot Factor	Insulation, inches	
		Depth	Width
2,200	0.35	1.25	0.18
4,400	0.35	1.50	0.25
6,600	0.33	1.50	0.32
13,000	0.27	2.00	0.55

Table 2. Usual Maximum Magnetic Densities

Part	25 Cycles	60 Cycles
Armature core...	90,000	80,000
Armature teeth..	100,000	85,000
Air gap.........	50,000	45,000
Rotor teeth.....	100,000	100,000
Rotor core......	90,000	90,000

THE MAGNETIC CIRCUIT is adjusted so that the magnetic densities are about as given in Table 2. In the stator and rotor teeth and in the air gap the density is not uniform, so that the maximum density (in the center of a field pole) is about 1.5 times the average density (see Polyphase Induction Motors). For a preliminary design this ratio may be assumed.

The Length of Air Gap is much influenced by its function in ventilation. For the electrical characteristic of the machine it is found desirable to have the length such that the ampere-turns excitation expended in the gap at no load and normal voltage are about equal to the armature reaction at rated load.

No Load Magnetization Curve. This is calculated as for induction motors (q.v.) on account of the distributed field winding and the peak wave of flux. The average densities are figured on a basis of full pitch pole arc and all stator teeth per pole carrying flux. The maximum density in gap, stator teeth, and rotor teeth is 1.5 times the average for a construction as in Fig. 5, with a pole center of 60 deg. With saturation in the teeth (over 110,000), or with specially wide pole centers, this constant becomes 1.45 or 1.40, respectively.

On account of the long air gap (long compared to slot openings and duct widths) the effect of slots in contracting the flux in the gap is not marked, so that the density in the air gap may be taken the same as at the surface of the rotor. Investigation shows that the increase in density in the air gap due to the slots is only from 2 to 4 per cent, and this is balanced by figuring the density at the surface of rotor instead of at the mean gap diameter. The section of rotor teeth is figured at a point one-third the distance from the bottom of the slots, and the total section includes the one large center tooth and several smaller teeth.

The average length of the path of the magnetic flux in the two cores is considerably less than one-half the pole pitch on account of the distributed flux. It is usually about 50 to 60 magnetic degrees.

The materials used are generally silicon steel for the stator and forged steel for the rotor. The tendency of the flux to pass through the slots instead of the teeth is not so great in these machines as in other types because, in the rotor, the flux can spread out with saturation, and in the stator, the densities are not very high. A magnetization curve between no load volts between terminals and ampere-turns per pole is usually plotted up to a voltage 120 per cent of rated voltage.

Rotor Slots. The rotor teeth must be carefully considered to determine whether there is sufficient material and strength at the root of the tooth to withstand the centrifugal force due to the masses of the tooth and the material in the slot. The force is $f = \frac{mv^2}{r}$, where m is the total mass, v the peripheral velocity at the radius of gyration, r. If $m = W/g$ in pounds, v = feet per second, and r = feet, then the force, f, is in pounds.

Approximately one-third of each pole pitch is left without slots or winding to form the center of the magnetic pole. This space is usually 60 electrical degrees between slot centers; thus in Fig. 5 there is a total of 16 slots for two poles, 8 slots per pole, and 4 coils per pole.

Table 3

Coils	Slots	Angle	1/2 Angle	Sin 1/2 angle
Coil in slots..................	4 and 5	60	30	0.50
	3 and 6	94.3	47.2	0.73
	2 and 7	128.6	64.3	0.91
	1 and 8	162.3	81.2	0.99
				3.13
Effectiveness of field, average..	... .	....	....	0.783

The slot pitch is determined by the fact that there are 8 slots and 7 teeth in 120 deg, thus the spacing is 120/7 or 17.15 deg. In some cases the slots are spaced as if there were to be 50 per cent more slots than are actually cut, in the example as if 24 slots at 15 deg were to be used but only 16 are actually cut, leaving smooth two spaces of 4 slots each. This would give a pole center of 75 deg and a lower ratio of maximum to average flux density in the air gap. The slots are very deep compared to their width; 6 to 1 is not unusual.

In some cases the slots have a narrow tunnel at the bottom underneath the winding, to carry ventilating air, and this air is let out along the length of the air gap by radial holes or air ducts, 3 to 6 in. apart, in the teeth.

ARMATURE LOSS. This is calculated and measured as in salient-pole machines (page 9–11) but the insulation used is of a higher grade and the copper is permitted to operate at a higher temperature so the losses are figured for a temperature of 100 deg cent. The mean length of a turn is longer because the straight portion of the coils projects from 1 to 2 in. beyond the core before it bends, thus adding 4 to 8 in. to the length of a turn. The total I^2R loss should be from 0.4 per cent in small machines to 0.2 per cent in a machine of 100,000 kva. The load loss in a 60-cycle machine is sometimes as great as the true resistance loss.

ARMATURE LEAKAGE REACTANCE. This is the same as in salient-pole machines, though lower in percentage because of the large number of slots per pole.

EXCITATION AT RATED KVA. Because the field winding is not concentrated in one coil per pole as in salient-pole machines it is not as effective in overcoming the armature reaction. The field acts as any distributed winding with fractional pitch, and the effectiveness of any one coil is proportional to the chord or to the sine of one-half the angle it subtends as shown in Table 3. The mmf to overcome the armature reaction is equal to the armature reaction divided by the effectiveness of the field which, usually has values around 0.8. Thus, letting n represent this mmf to overcome armature reaction, the excitation for any load at any power factor can be calculated by the method given on page 9–13.

FIELD COILS. Each of the several concentric field coils consists of 10 to 40 turns of flat wire wound on edge with about 5 mils of insulation between turns and about 100 mils of mica or asbestos insulation on the outside of the coil. These coils are placed deep in the slots, leaving fully 1/2 in. above the wedge for the ventilating air. The wedge is made very strong because it must hold the coil against enormous centrifugal forces. For this reason the field slot factor is low considering the voltage used, factors between 0.4 and 0.6 being usual. The field coils are the hottest part of the machine and, being insulated with mica or asbestos, can operate at temperatures from 100 to 150 deg cent with 125 as a common practice. The loss may be 0.9 watt per square inch of total coil surface for a rise of about 90 deg cent. The end connections are supported by a non-magnetic metal retaining ring, shrunk on tightly, to give an initial compression at standstill so there will be no movement of the coils between standstill and full speed. The fields are frequently proportioned to give rated voltage at rated kva output at 80 per cent inductive power factor with an exciter voltage of 200 out of 250, but this is a difficult specification to meet.

EFFICIENCY AND LOSSES. The losses are friction, excitation, core loss, armature I^2R loss, and load loss. The last two are usually combined and referred to as the armature short-circuit loss as it is obtained from the short-circuit test. The principal friction is that due to windage, and this is primarily the power required to ventilate the machine. The theoretical friction loss in ventilation is

$$\text{Kw} = 0.000273 \times (\text{cu ft per min}) \times (\text{pressure in oz})$$

and the actual loss is this amount divided by the efficiency of the blower and the motor. The usual pressure is 4 to 8 oz, or 7 to 14 in. of water. The excitation loss is the $I^2 R$ in the field as explained above and excludes the loss in the field rheostat. The core loss is proportional to the maximum densities in each part and to the quality of the material, which is usually silicon steel having $\eta = 0.001$ and $\epsilon = 0.00007$. Because of the long air gap and the simple flux wave the test values can be quite closely predicted by calculation. It will be noted in Table 4 that the friction loss is not only the greatest item but makes up almost one-half of the total loss.

Table 4. Usual Efficiencies and Losses of Turbo-generators

For non-inductive load

Kva	Per Cent Efficiency	Per Cent Friction	Per Cent Excitation	Per Cent Core Loss	Per Cent Armature
2,000	96	1.50	0.70	1.20	0.60
5,000	97	1.20	0.45	1.00	0.35
10,000	97.5	1.00	0.35	0.90	0.25
20,000	98	0.80	0.25	0.77	0.18
30,000	98.2	0.70	0.20	0.75	0.15
100,000	98.3	0.70	0.20	0.65	0 15

SYNCHRONOUS IMPEDANCE is very high on these machines and the steady short-circuit current correspondingly small. It is frequently the case that, with excitation for rated voltage and no load, the short-circuit current is less than the rated load current. Thus voltage regulation by external means is absolutely necessary, the inherent regulation being from 20 to 30 per cent at unity power factor and rated load.

6. TESTS OF ALTERNATING-CURRENT GENERATORS

(See also Standardization Rules of the A.I.E.E.) The principal tests are

Magnetization or saturation test.
Core-loss and friction tests.
Synchronous-impedance test.
Load-loss test.
Resistance measurements.
Heat runs.
Insulation tests.

Examples of test results are given below; typical test curves are given in Fig. 10.

MAGNETIZATION CURVE. The magnetization curve, popularly named the no-load saturation curve, shows the relation between the no-load voltage and the current in the field. Fig. 11 shows the connections for making this test. On account of the existence of the hysteresis loop (see article on Magnetic Properties of Iron), it is necessary, in running this test, to increase the field current gradually from point to point and never reduce the value at any step until the highest excitation has been obtained. The curve differs in shape from the magnetization curve of a closed sample of iron because the magnetic circuit of the alternator contains a considerable air gap, the magnetization curve of which is a straight line. Therefore, if the saturation curve of a machine contains a portion which is very straight, the indications are that the air gap is of considerable magnitude. If the machine is operated at very high magnetic densities, this is indicated by the fact that the point corresponding to rated voltage is found at a point on the curve where it is nearly horizontal.

The magnetization curve is usually plotted in terms of the volts between terminals. In comparing the observed and calculated magnetization curve it should be noted that the calculations are expressed in terms of the volts per phase.

CORE LOSS AND FRICTION. The open-circuit or true core-loss curve shows the core loss in watts for each value of the no-load terminal voltage. It is made by driving the generator at rated speed by means of a small motor, the efficiency of which is known, and varying the generator excitation. Fig. 11 shows the connections for this test. The voltage and mechanical power P (=input to motor multiplied by its efficiency) required for each value of excitation are noted. The power P_0 for zero excitation is the friction loss in the machine. The core loss for any excitation is $P - P_0$. The no-load saturation curve can be made at the same time as the core-loss test.

SYNCHRONOUS IMPEDANCE. The synchronous-impedance curve shows the relation between various values of field current, or excitation ampere-turns, and the

current that flows in the armature on short circuit. It is made by short-circuiting the armature through ammeters and operating at full frequency with various values of field current. Fig. 12 shows the connections for this test. Of course only fractional values of

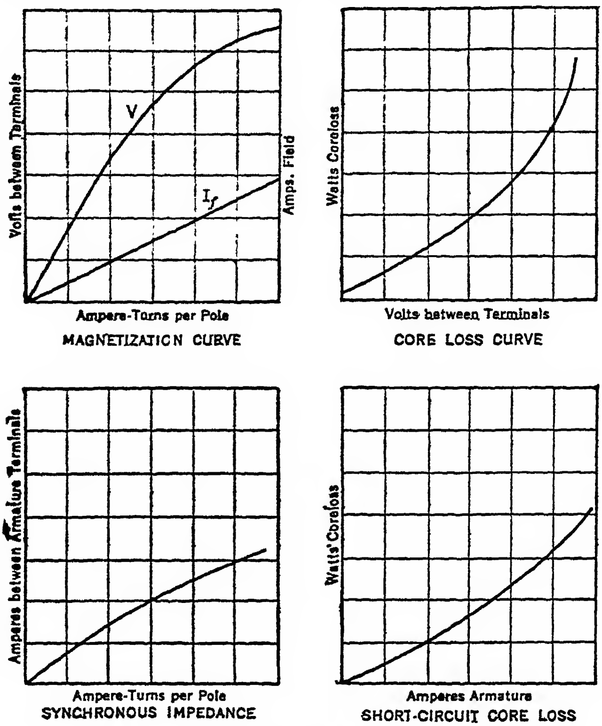

Fig. 10. Typical Test Curves

normal excitation are used, or the current in the armature would be so great as to cause damage.

The synchronous-impedance curve gives approximately the ampere-turns corresponding to armature reaction and the leakage reactance drop in the armature combined, i.e., the ampere-turns corresponding to the synchronous reactance. The approximation

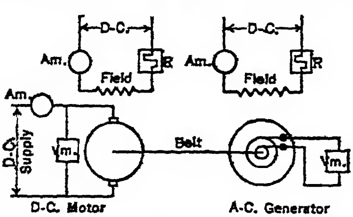

Fig. 11. Connections for Magnetization Curve, Core Loss and Friction Tests

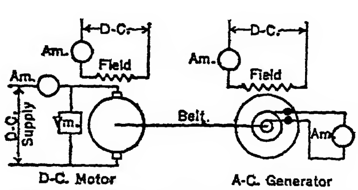

Fig. 12. Connections for Synchronous Impedance and Load Loss Tests

arises from the effect of the armature resistance and the low saturation or magnetization of the magnetic circuit under the short-circuit conditions.

STRAY LOAD LOSSES. These include iron losses, eddy-current losses in both copper and iron, due to leakage fluxes caused by and varying with the load current and also varying with the saturation in the iron. The load losses may be obtained at the same time and with the same set-up as the synchronous impedance test. The output of

the driving motor is accurately calculated, and from this is subtracted the friction of the machine under test (known) and the armature I^2R, calculated for the proper temperature, and the remainder is the load loss for the particular armature current.

The following is quoted from the Standardization Rules of the A.I.E.E.: Stray load losses shall be determined by operating the machine on short circuit and at rated load current. This, after deducting the windage and friction and I^2R loss, gives the stray load loss for polyphase generators and motors. These losses in single-phase machines are large; but the Institute is not yet prepared to specify a method for measuring them.

RESISTANCE MEASUREMENTS must be made when all parts of the machine are at some known temperature. They are also made after the heat run, when the machine is hot, to check the temperature as measured by thermometers.

Field Resistance is measured by the simple voltmeter-ammeter method.

Armature Resistance. The armature resistance between terminals is also measured by the simple voltmeter-ammeter method, by connecting two of the terminals to a source of direct current (the other terminal being free), the rotor (field or armature of course being at rest). For a single-phase or two-phase machine the resistance as thus measured is the resistance per phase. For a three-phase machine, let R_t = the resistance as thus measured and R_p = the resistance per phase. Then for a Y-connected armature $R_p = R_t \div 2$, and for a Δ-connected armature $R_p = 3R_t \div 2$. If the connection is not known, the calculation of the resistance drop and copper loss may be figured correctly, assuming it either Y or Δ connected, provided the resistance per phase and current per phase are both calculated on the same assumption regarding the connection. For a two-phase machine the resistance between terminals A and B and between B and C (B being the common terminals) should each be measured, and the average taken. For a three-phase machine the resistance between A and B, B and C, and A and C should be measured and the average taken.

CALCULATION OF REGULATION AND EFFICIENCY FROM TESTS. From the results of the preceding observations, the regulation and efficiency of the machine at various loads may be calculated by the methods given above, in the discussion of Predetermination of Performance, using the test data instead of the calculated quantities. See Standards of A.I.E.E. The synchronous-reactance ampere-turns may be taken as equal to the synchronous-impedance ampere-turns, since the resistance drop in the armature on short circuit and reduced excitation is seldom over 10 per cent of the synchronous-reactance drop, and as the two are in quadrature the synchronous-impedance drop differs from the synchronous reactance drop by less than 1 per cent. In using the magnetization curve and the synchronous-impedance curve one must keep in mind whether they are plotted in terms of voltage and current per phase or in terms of volts between lines and line current.

FULL-LOAD SATURATION CURVE. This curve shows the relation between the terminal voltage and field current with full-load current in the armature. It may be plotted from tests or calculated from the magnetization curve and the synchronous impedance in the same manner as the regulation is calculated.

ARMATURE LEAKAGE REACTANCE. There are three methods by which the leakage reactance may be determined:

(1) Synchronous-impedance Method. This gives only approximate results but is very generally used as a synchronous-impedance test is made on every generator. Let n be the field ampere-turns per pole required to force full-load current through the short-circuited armature. Let a be the calculated armature reaction ampere-turns per pole (see above), with rated current. Then $n - a$ is the excitation necessary to induce the leakage reactance voltage (IX) in the armature. From the open-circuit saturation curve find the voltage corresponding to $(n - a)$ ampere-turns. Reducing to volts per phase, if necessary, and dividing by the current per phase, the result is the leakage reactance X per phase in ohms.

(2) Full-load Characteristic Method. This method is also approximate. Let the excitation in ampere-turns per pole required to give rated voltage at full non-inductive load be q. Let the ampere-turns to give rated voltage without load be m. Then $n = \sqrt{q^2 - m^2}$ is taken as the synchronous-reactance ampere-turns, and the leakage reactance is calculated as described in the preceding paragraph.

(3) Inductance-measurement Method. This method gives exact values, but is not very often employed. From an external source of proper frequency, full-load current is sent through the armature of the machine to be tested, with the fields excited to the normal value but not rotating. The voltage drop across the armature terminals is measured for several different positions of the coils with respect to the poles, ranging through an arc of about one-half the pole pitch. Let Z = the voltage per phase divided by the current, R = the resistance per phase corrected for load loss (i.e., the effective

resistance as determined from the short-circuit core-loss curve); then the leakage reactance per phase is $X = \sqrt{Z^2 - R^2}$. This reactance will vary with the position of the coils and the maximum and minimum may be found by making this calculation for the different positions of the coils with respect to the fields.

HEAT RUNS are made at rated load and various other specified loads. The parts in which the rise in temperature is of interest are:

Armature core surface.
Armature core ventilating ducts.
Armature conductors.
Collector rings.
Both pole tips.
Field winding.
Bearings.
Frame.
Room.

The temperature of the field and armature winding should be measured both by thermometers and by the resistance method. In taking the temperature of a hot surface by thermometer a small pad of waste should be placed over the bulb after the thermometer is put in place. The pad should not be too large or it will prevent the normal radiation from the surface.

With large machines it is inconvenient and expensive to test under full-load conditions. For determining the heating without actually developing the full power of the machine several methods are available.

Reversed-field Method. The field circuit may be tapped and the full-load field current sent through a portion of the field coils in a direction opposed to that for normal operation. For example, in a 24-pole machine the current in 8 of the field coils may be directed in such a manner that they are reversed with respect to the remaining 16. The armature winding will therefore generate a voltage due to the 8 poles that are not neutralized and therefore of approximately one-third rated value. If the armature is short-circuited a current will flow due to this reduced voltage, and this current can be made to approximate closely the full-load value by making a proper division of the poles. If the machine is operated under these conditions the friction, excitation, core loss, and armature copper loss will be very nearly equal to their value under normal operating conditions, yet to drive the machine only an amount of power approximately equal to the sum of the losses is required.

Synchronous-motor Loading. If two machines are available they may be connected up as a generator and synchronous motor and the field excitation of the motor adjusted so that a current of full-load value, but having a large reactive component, will flow in the armature, the power factor being nearly zero. The power required to drive the generator at full-load excitation and at full-load current will then be small.

Direct-current Loading. Full-load losses may be simulated on a three-phase generator by connecting the three phases in delta and leaving the delta open at one point, to which a d-c ammeter and a source of direct current may be connected in series. The delta is first closed through an a-c ammeter and the triple-frequency current in the delta (see Alternating Currents) is measured. The d-c ammeter and source of direct current are then connected in series with the delta and the direct current increased until the sum of the squares of the local current of triple frequency and the direct current is equal to the square of the rated current per phase.

Open-circuit Short-circuit Method. Another ingenious method, advocated by Hobart, consists in alternating open-circuit and short-circuit tests, each under exaggerated conditions, so that at the end of each hour the total watthours lost in each part are equal to the watthours that would be lost in normal operation. For example, let the core and field copper loss combined be 4 kw, and armature copper loss 1 kw. If, now, the machine is operated for 20 minutes with armature short-circuited and the excitation adjusted to give 3 kw copper loss, and for 40 minutes on open circuit with excitation adjusted to give 6 kw core and field copper loss, then the loss per hour in the armature copper is 1 kwhr, and in the field winding and core 4 kwhr, the same as under normal conditions. For an exact division of the time between the open-circuit and short-circuit conditions, the core and field copper loss during the short-circuit run must be taken into consideration. After several hours of this relaying the machine will have reached a temperature corresponding to full-load operation.

INSULATION TESTS. The insulation of a machine is usually tested by applying a given voltage between the conductors and the part of the machine from which they are insulated. An insulation resistance test is also made.

Voltage Tests. During manufacture the coils are tested separately, and after the machine is assembled a voltage test between the completed windings and frame is made. After the heat run, while the machine is still warm, a third test of the insulation between windings and frame is made.

For this third test an alternating voltage is applied between armature and frame, according to the Standardization Rules of the A.I.E.E. (q.v.).

The voltage should be increased gradually, and the final value should be applied for 1 minute. In this test the machine acts as a condenser and therefore care should be taken that the frequency is not so high or the inductance of the supply circuit so great as to set up resonance. It is advisable to have considerable resistance in the supply circuit.

To prevent an uneven distribution of voltage, all the terminals of the winding should be connected together by fine wires and one terminal of the high-potential circuit connected to the common connection. The high potential should be measured by a spark gap connected in shunt to the machine.

INSULATION RESISTANCE. The insulation resistance is measured by connecting one terminal of a 500-volt d-c supply to the windings of the machine through a voltmeter with a 500 scale, and connecting the other 500-volt terminal to the frame. If the resistance of the voltmeter is R_v ohms and the voltmeter deflection x, the insulation resistance $R = \frac{R_v}{x}(500 - x)$. The required value is:

$$\text{Megohms} = \frac{\text{Rated voltage}}{\text{Rated kva} \times 1000}$$

7. EXAMPLES OF DESIGN AND PERFORMANCE

In Tables 5 and 6 will be found the essential data both of the mechanical and electrical features of ten representative alternators.

8. OPERATION

In the operation of an a-c generator the following factors should be considered:

PHASE CONNECTIONS AND GROUNDING. When a third harmonic is present in the emf wave of a three-phase generator, the triple-frequency emf's in the three phases (or windings) are additive when the three phases are connected in Δ, that is, the Δ forms a short circuit to the third harmonic emf's and a large triple-frequency current may therefore be set up in the windings irrespective of the load on the machine. On this account, large three-phase generators are usually Y-connected, since with this connection the third-harmonic emf's between any two terminals of the machine neutralize each other. However, when two or more Y-connected machines are operated in parallel with their neutrals grounded, a triple-frequency cross-current of considerable magnitude may be

Table 6. General Dimensions and Design Constants of Turbo-generators

set up between the machines, unless the wave forms of the emf's of the various generators are exactly the same, which is practically never the case. To prevent such cross-currents with Y-connected machines with grounded neutral, it is the usual practice to ground the neutral of but one generator at a time. Provision must of course be made to shift this ground connection from one machine to any other, so that a ground connection can always be maintained irrespective of which machine or group of machines may be running.

DIVISIONS OF LOAD BETWEEN ALTERNATORS IN PARALLEL. The division of load between two or more alternators operating in parallel cannot be changed by altering their field excitation, as it can with d-c generators. Changes in the load taken by any alternator of a group can be effected only by admitting more or less steam to the driving engine or turbine (or water to a water-wheel). In order that the various alternators shall share the combined load properly, it is therefore necessary that the governors on the several prime movers give the same speed-load characteristics.

Although the field excitation has no effect on the distribution of the load among the alternators, it does affect the power factor of the load delivered by each machine. The excitation of each alternator should be so adjusted that it delivers its load at the same power factor as the others.

STARTING A SINGLE GENERATOR. Before a generator is started up its bearings must be inspected and cleaned and filled with oil if necessary. The machine is then brought up to the proper speed and the bearings again inspected to see that the oil-rings are running properly. The exciters or excitation circuit is then put in readiness and the rheostat in the alternator field circuit adjusted for maximum resistance. Before exciting the field the armature insulation must be thoroughly dry. If it is not the armature should be short-circuited through an ammeter and run for several hours at a partial excitation to give about rated current in the short-circuited armature. When the insulation is thoroughly dry the short circuit is removed and the excitation adjusted to give rated voltage at the armature terminals with correct speed. To shut down the machine the load is first removed by opening the circuit breaker; then the field rheostat is turned to maximum resistance, as is also the rheostat in the exciter field if there is an individual exciter. Then the field circuit is opened.

PARALLELING OF GENERATORS. Before connecting a generator to bus-bars to which one or more other generators are connected, the following conditions must be satisfied:

1. The frequency of the generator must be the same as that of the bus-bars.
2. The frequency of the generator, and therefore its speed, must be constant for an appreciable interval of time.
3. The voltage of the generator must be the same as the voltage of the bus-bars.
4. The generator and bus-bar voltage must be in phase.

If the two machines have not the same frequency or if the frequency is not constant, a condition will occur intermittently in which the two voltages are 180 deg apart or the two machines are in series on a short circuit, and a dangerous current will flow. If the voltages are not equal, a large "wattless" or reactive current may flow, and if the two

voltages are not in phase, a large power current will flow which will cause a mechanical shock. To indicate when these conditions are fulfilled any one of several "synchronizing" devices may be employed, as described in the article on Synchronizers and Synchroscopes.

Synchronizing with Lamps. The simplest method of synchronizing small machines is to use incandescent lamps as shown in Fig. 13. In Fig. 13A, the connections are such that the lamps remain dark when the above conditions are satisfied, whereas in Fig. 13B they will remain bright under these conditions. If the frequencies are wrong the lamps will flicker (the slower the flicker the nearer the two frequencies). If the voltages are wrong the lamps in 13A will glow slightly but steadily. Transformers should be used with the lamps in high-voltage machines.

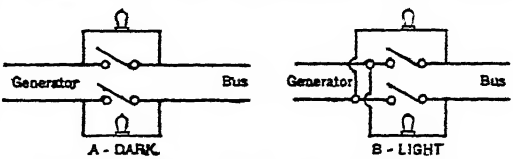

FIG. 13. Connections of Lamps for Synchronizing

HUNTING. Unless the angular velocities of two machines which are connected in parallel remain the same, either both constant or both varying together, a cross-current will flow, due to the phase displacement between them. This current will tend to drag ahead the machine which is lagging, but owing to the inertia of the rotating parts the machine which is at first lagging will "overreach" and become leading, and under certain conditions a cumulative seesaw action will be set up. When this takes place the machines are said to "hunt." The value of this current is proportional to the short-circuit current of the machines and to the angular displacement expressed in electrical degrees. In a machine having a large number of poles (40), a very small variation in angular displacement of the prime mover may cause a considerable (20-fold) phase displacement in electrical degrees.

To prevent hunting it is necessary to have:

1. A prime mover giving reasonably constant tangential effort and angular velocity. In general, the maximum variation in angular displacement between any machine and the bus-bars should not exceed 2.5 electrical degrees.

To secure this condition the machines should have constants such that they are not especially sensitive as pendulums to the strokes or impulses of the particular engines used.

2. A governor which is not too sensitive to slight and sudden variations in load, i.e., a damped governor.

3. A low-resistance drop (usually not over 10 per cent) in the connections between the machines. This refers particularly to groups of machines in power houses miles apart.

4. Short-circuited or "amortisseur" windings on the fields of the machines. Currents induced in these windings cause them to act as electrical brakes.

SHORT CIRCUITS. An alternator, when suddenly short-circuited, will deliver, for an instant, a current many times as great as will flow after conditions have become steady. This is due to the fact that it takes a definite period of time for the increased armature reaction to weaken the main magnetic field. During this period much damage may be done to windings and circuit breakers. This transient short-circuit current has a nominal or symmetrical effective value of $E \div X$ or the rated current multiplied by $\frac{100}{\%IX}$, but it may have a maximum instantaneous value of $2\sqrt{2}$ times this depending upon the part of the cycle at which the short circuit starts.

Use of External Reactance. Frequently, therefore, reactance or choke coils are connected in circuit with these machines to prevent a dangerous current flowing in case of sudden short circuit. See Reactance Coils.

Induction Generators on Short Circuit. Induction generators are free from this fault, since they lose their excitation almost immediately on short circuit, and are therefore becoming popular in large central stations.

USE OF IMBEDDED THERMOMETERS. In large generators thermocouples or resistance theremometers (see Pyrometers) are sometimes imbedded in the estimated hottest spot of the winding, and connected to a suitable indicating device to show at all times the maximum temperature of the machine. See also Standardization Rules of the A.I.E.E.

9. SPECIFICATIONS FOR A-C GENERATOR

The following memoranda are intended to assist in writing specifications.

Principal Characteristics and Conditions of Service. Service for which generator is to be used, such as a-c lighting, single-phase railway service, operating synchronous

converters for railway or lighting, etc. Voltage and number of phases. Rated output in kilowatts or kilovolt-amperes at stated power factor. Frequency and speed.

Style and Description; Details of Construction. Type of generator, revolving field, induction type, etc. Details of speed, governing of prime mover, and how generator is connected to prime mover, e.g., direct or belt-driven by steam turbine, reciprocating engine, water wheel, water turbine, gas engine, oil engine, etc., with vertical or horizontal shaft. Whether compensated. Whether exciter is to be supplied; if so, its characteristics. If field rheostat is to be supplied, its characteristics, including the effect upon the generator voltage of each step and of all steps; whether to be controlled by hand or automatically. Restriction of excitation current and voltage and requirements respecting carrying capacity of slip rings. Accessibility of armature. Whether imbedded thermometer coils shall be furnished. Windings shall be clamped securely to prevent any vibration of overhanging parts. Mechanical protection of armature conductors if exposed. If belt driven, specify pulley details; whether bed plate is desired.

Work to be Done by Other Contractors. Whether contractor is to furnish and install the following: main wiring, field wiring, field rheostat grids, dial plate, and chains. Point of division between engine and generator contracts.

Performance and Tests. (*See Standardization Rules of the A.I.E.E.*) Temperature rises upon which ratings are to be based. Details of overload capacity. Efficiency at 25, 50, 75, 100, and 125 per cent load. High-potential tests of insulation. Requirements regarding effects of moisture upon insulation. Requirements for parallel operation, i.e., whether the machine is to operate in parallel with similar machines or different ones. It is usual to specify that the terminal voltage shall vary according to a sine law. Regulation with 100 per cent power factor and normal speed; the load may be varied from zero to 150 per cent of rated load without causing more than a stated variation of voltage, the exciter field being kept constant.

SYNCHRONOUS MOTORS

Any alternator will operate as a motor. If two synchronous alternators are connected in parallel to bus-bars supplying a load, and the driving power be removed from one prime mover, the alternator connected to this prime mover will continue to run at the same speed as before, taking power from the other alternator and driving its own prime mover or other apparatus coupled to it; i.e., this alternator acts as motor. The speed of such a motor depends solely upon the speed of the generator or generators supplying electric energy to it; it is therefore said to run in "synchronism" with the source of supply and is called a synchronous motor. The synchronous speed of a synchronous motor having p poles, when supplied with a current of a frequency of f cycles per second, is

$$N = \frac{120f}{p} \qquad \text{rpm}$$

If the load on such a motor increases, the speed will not decrease, unless the load reaches such an excessive value that the maximum output or "pull-out torque" is reached, when the motor will drop out of step and come to rest, the current taken increasing to short-circuit value and the torque decreasing to a negligible value.

DIFFERENCES BETWEEN AN ALTERNATOR AND SYNCHRONOUS MOTOR. The difference in construction between an alternator and a synchronous motor is that the latter has placed in the face of the field poles, a squirrel-cage winding, which is intended to give good starting torque and to prevent hunting while running. A synchronous motor usually operates better with a higher value of armature reaction than that of a well-designed generator of the same kilowatt rating. This increase in armature reaction is usually obtained in practice by operating the machine as a motor at lower voltage than that for which it would be operated as a generator. Thus a standard 2300-volt generator will operate very satisfactorily as a motor at 2080 volts, and as these are the natural values of the generated and delivered voltages, this characteristic of the synchronous motor fits in very well with customary distribution practice. Thus a standard generator may have a squirrel-cage winding added to its poles and become a good synchronous motor.

FIELD EXCITATION. Synchronous motors always require direct current for field excitation, and if a suitable d-c source is not available an exciter must be provided.

NUMBER OF PHASES. Synchronous motors may be single, two, or three phase. The single-phase motor is not self-starting and has a considerably lower efficiency than the polyphase motor. It is also more likely to hunt (see below) and be unstable, and is therefore far less desirable than a polyphase motor. The two-phase and three-phase motors are very similar in all their characteristics. There is a slight economy in the three-phase over the two-phase motor as there is in the three-phase over the two-phase generator (q.v.).

TERMINAL VOLTAGE. Since synchronous motors are usually built with a revolving field and a stationary armature, it is possible to insulate the armature winding for voltages as high as 13,000 and thus obviate the need of transformers in many cases.

ADVANTAGES AND DISADVANTAGES OF SYNCHRONOUS MOTORS. The advantages of synchronous motors as compared to induction motors are: higher efficiency, higher power factor, controllability of power factor, constant speed, higher voltage, lower cost. The disadvantages are: need of an exciter, possibility of hunting.

RELATIONS OF VOLTAGE AND CURRENT. The relations between line voltage and phase voltage are the same as in a-c generators (q.v.). The current in each line of a three-phase motor is

$$I = \frac{746\,P}{\sqrt{3}\,\epsilon E \cos\theta}$$

where P = horsepower output.
E = voltage between lines.
ϵ = efficiency at load assumed.
$\cos\theta$ = power factor (may be unity).

Usual values for efficiency are about the same as for a-c generators (q.v.).

APPLICATIONS. In order to transform from alternating to direct current, or from one kind of alternating current to another differing in frequency, potential, or phase relation, motor-generator sets, consisting of a synchronous motor direct connected to one or more generators, are often employed. By this means the potential of the secondary or distribution circuit is independent of the variation in potential of the primary circuit supplying power to the motor. In certain cases it is desired to take power from a 25-cycle circuit and supply power at 60 cycles for lighting purposes. Here a synchronous motor-generator set would be used. Such a set is frequently called a "frequency changer" (see Frequency Changer). In some applications of electric drive by induction motors one synchronous motor is installed for the purpose of making it take leading current in order to neutralize the lagging current taken by the induction motors. This effect is produced by over-exciting the fields of the synchronous motor. Such a synchronous motor is called a "rotary phase modifier" or "rotary condenser." It may incidentally be used to drive any machinery that does not require a large starting torque.

10. GENERAL PRINCIPLES

In any synchronous generator or motor when a current flows in the armature there is a loss of voltage proportional to IZ_0, where I is the current and Z_0 is a hypothetical quantity called the synchronous impedance, which includes the effect of the resistance, the leakage reactance and the demagnetizing effect of the armature current. This quantity is obtained by the synchronous impedance test (see below) and is expressed in complex quantities as $Z_0 = r + jx_0$ and in algebra $Z_0^2 = r^2 + x_0^2$, where r is the effective resistance per phase and x_0 is the synchronous reactance per phase. IZ_0 is therefore the drop in voltage per phase in the armature, and this voltage and the current differ in phase by an angle θ, where $\tan\theta = x_0/r$ and $\cos\theta = r/Z_0$. If a synchronous motor

is running and generating a counter emf e and is connected to bus-bars of voltage E, the current flowing in the armature will be proportional to the vector difference between E and e and inversely proportional to Z_0, all taken per phase.

VECTOR RELATIONS FOR MOTOR ACTION. In Fig. 1 let E represent the bus-bar or line voltage (per phase) impressed on the terminals of a synchronous motor. Let e represent the counter emf of the motor, and in this case assume $e < E$ and directly opposed to E. Then the difference between E and e will set up a current in the armature of the motor. IZ_0 will be the voltage, and the current will lag behind IZ_0 by an angle θ where $\cos\theta = r/Z_0$. Thus the motor takes a current I lagging behind the impressed voltage E.

Fig. 2 shows the relations when $e > E$, then IZ_0 will be reversed in phase as indicated.

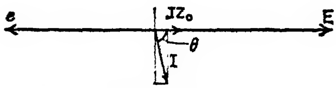

FIG. 1. Lagging Current

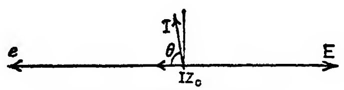

FIG. 2. Leading Current

I will always lag behind IZ_0 by the angle θ and will be found drawn upward. I lags behind e and IZ_0 but I leads the impressed emf E by an angle (180 deg $- \theta$). Thus when the field excitation is increased so that e tends to become greater than E, the machine takes a current leading with respect to the impressed emf. As in a synchronous generator the field excitation required for a given terminal voltage depends upon the phase relation of the external circuit or the load, so conversely in a synchronous motor the phase relation of the current into the armature at a given terminal voltage depends upon the field excitation and the load.

Fig. 3 shows the relations when e is more than 180 deg behind E, that is, e is behind the position it had in the preceding examples by an angle α. The vector resultant of E and e will be IZ_0 as shown, leading E. The current I will lag behind IZ_0 by the same angle θ, but is now almost in phase with E and lagging only slightly. Thus power ($EI\cos\phi$) is being sent into the machine and it acts as a motor, transforming electrical power into mechanical power. When the machine is running as in Figs. 1 and 2 the power is very small. If, however, a mechanical load is applied, the armature will drop back in position by a slight amount. This causes e to drop back in phase and the machine immediately draws power from the line.

If, as in Fig. 4, power is applied to make the armature move forward and cause e

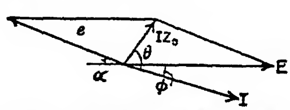

FIG. 3. Leading Current under Load Conditions

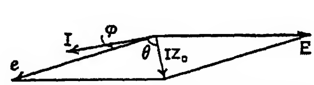

FIG. 4. Lagging Current under Load Conditions

to advance in the opposite direction, the resultant IZ_0 is thrown downward and I, lagging behind IZ_0 by θ, is thrown around almost in phase with e. The machine then becomes a generator, transforming the mechanical power applied into electrical power $eI\cos\phi$.

Synchronous Position. In the discussion of the action of a synchronous motor it is convenient to employ the term "synchronous position," by which is meant the position which any definite point on the revolving member occupies at the same period of each cycle of time. It is only necessary for the machine to change in synchronous position by a very slight angle α to cause a large energy current to flow. If α should become 90 deg, theoretically the power would become a maximum, and any increase in α means that θ becomes greater than 45 deg, the power decreasing and the machine falling out of step. When α becomes 180 deg a total emf equal to the sum of e and E is short-circuited by Z_0 and the current is enormous and the power factor low.

MAXIMUM TORQUE. If the speed changes for a short instant of time sufficiently to allow a point on the armature to drop back in synchronous position one-half the pitch of one pole (90 electrical degrees), the motor torque will increase from zero to the maximum available in the motor. Thus, for any torque less than the maximum the armature (or revolving field) need only change in speed sufficiently to drop back some distance less than one-half the pitch of a pole. If the load demands a torque greater than this maximum the armature will drop back more than 90 deg and will fall out of step and come to rest. In most synchronous motors the maximum torque is about 6 times normal torque.

11. DESIGN AND CALCULATIONS

The design and calculation of synchronous motors are very much like the design and calculation of a-c generators. There is a difference in the proportioning of certain details and there are certain features that are of importance in generators that are not important in motors (i.e., regulation) and the converse is also true.

ARMATURE REACTION. The armature reaction of a synchronous motor is expressed as $\frac{1.5\sqrt{2}\,SIk_2k_3}{p}$ for a three-phase machine and $\frac{\sqrt{2}\,SIk_2k_3}{p}$ for a two-phase machine, where S = turns in series per phase, I = full-load current per phase, k_2 and k_3 have the values given in the chapter on Alternating-current Generators and p = number of poles. The armature reaction of a motor is usually 30 to 50 per cent greater than that of a generator of the same rating and frequency. The higher value gives greater synchronizing torque per ampere and a better starting torque, and reduces the cross-currents between machines in case of hunting. The armature reaction ampere-turns at full load may be equal to the field ampere-turns at no load. Too great an armature reaction is objectionable, because it reduces the energy transfer between two machines and therefore reduces the synchronizing power, that is, the tendency of the machines to hold each other in step.

EXCITATION. The excitation of a motor is calculated in the same manner as that of a generator. The magnetic densities are usually a little less. The capacity of the field winding depends upon whether the synchronous motor is to be used as an ordinary motor or to regulate the power factor of a system by overexcitation.

LEAKAGE REACTANCE. The leakage reactance may be higher in a motor than in a generator as regulation is not of so great importance. However, too great a reactance will reduce the starting torque of the motor.

SHORT-CIRCUIT CURRENT AND SYNCHRONOUS IMPEDANCE. The short-circuit current of the motor depends upon the leakage reactance and the armature reaction. The short-circuit current and the synchronous impedance may be predetermined from the no-load saturation curve and the calculated leakage reactance per phase.

Let F = excitation in ampere-turns per pole for which it is desired to find the short-circuit current.
I = rated current per phase.
x = leakage reactance in ohms per phase.
E = voltage per phase due to F at no load.
S = turns in series per phase.
p = number of poles.

Then the ampere-turns synchronous impedance for full-load current is

$$\frac{2.12\,SI}{p} + \frac{IxF}{E}$$

and the short-circuit current with excitation F is

$$I_0 = \frac{EpF}{2.12\,SE + xpF}$$

The synchronous impedance at this excitation is $Z_0 = E/I_0$, and the synchronous reactance is $x_0 = \sqrt{Z_0^2 - r^2}$, where r is the resistance of the armature per phase.

EFFICIENCY AND LOSSES. The losses are predetermined as in a generator. They are: A = friction, B = excitation or field RI^2, C = core loss, D = armature RI^2; then

$$\text{Efficiency} = \frac{\text{Output}}{\text{Output} + A + B + C + D}$$

PHASE CHARACTERISTICS OR V-CURVES. The phase characteristic is a curve showing the variation in armature current for any given load with varying field excitation. Fig. 5 shows the shape of the curves, which may be determined both by calculation and test. The phase characteristic for any particular load has the general

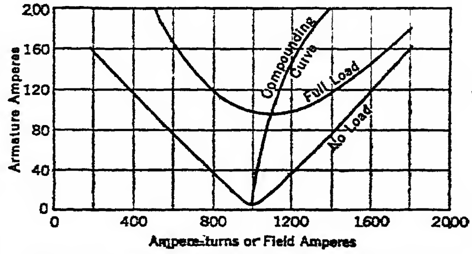

FIG. 5. Phase Characteristic of Synchronous Motor

shape of the letter V, and the group of such curves for various loads are frequently called the "V-curves" of the machine. There are two methods of calculating the phase characteristics, the electromotive force method and the magnetomotive force method.

Electromotive Force Method.

Let E = line voltage per phase.
e = motor counter emf per phase corresponding to the excitation to be used.
i = component of current in phase with e.
ei = mechanical output of armature.
i_1 = reactive component of current, positive for leading, negative for lagging.
r = armature resistance per phase.
x_0 = synchronous reactance per phase.

Then $E^2 = (e + ri - x_0 i_1)^2 + (x_0 i + ri_1)^2 = e_1^2 + e_2^2$.

E, r, and x_0 are constant, e is set by the value of the field current assumed, then i = (watts output)/e and i_1 remains the only unknown quantity. Solving for i_1, the total current $I = \sqrt{i^2 + i_1^2}$, and the power is $e_1 i - e_2 i_1$ (for i_1 lagging). If e is greater that E, then i_1 is leading, and the power factor is $(e_1 i + e_2 i_1)/EI$.

Magnetomotive Force Method.

Let E = line voltage per phase.
F = field ampere turns per pole for this voltage.
D = any value of field ampere turns per pole.
I = armature current per phase.
i = energy component of current = (power input) ÷ E.
p = number of poles.
ν = field leakage coefficient of machine.
S = turns in series per phase.
i_1 = wattless component of current for excitation D.

Then
$$pF = pD - 2.12\, Si_1 \nu$$
$$i_1 = \frac{pD - pF}{2.12\, S\nu}$$

and $I = \sqrt{i^2 + i_1^2}$ is the current in armature for power input Ei and for the excitation D assumed. If i_1 is negative $(F > D)$ then i_1 is lagging. If $D > F$ then i_1 is positive and leading.

ANGULAR LAG DUE TO LOAD (β). For any load on a synchronous generator there is an angular advance of the generated emf ahead of the terminal emf, and in a synchronous motor there is an angular lag of the generated emf behind the impressed emf. This phase displacement is accompanied by a shift in the synchronous position of the armature, which may be calculated and actually measured (see Tests of Synchronous Motors below).

To calculate this angle β expressed in electrical degrees (360 deg per pair of poles), let

E = line or terminal voltage per phase.
e = induced or counter emf per phase; may be taken from no-load saturation curve for given excitation.
r = resistance of armature per phase.
x_0 = synchronous reactance per phase.
I = current per phase.
ϕ = phase angle between E and I.

Then
$$e^2 = (E - Ir\cos\phi - Ix_0\sin\phi)^2 + (Ir\sin\phi - Ix_0\cos\phi)^2$$

and
$$\beta = \sin^{-1}\left[\frac{(Ir\sin\phi - Ix_0\cos\phi)}{e}\right]$$

or roughly
$$\sin\beta = \frac{I\cos\phi}{\text{Short-circuit current}}$$

The mechanical displacement of the armature for the load input $EI\cos\phi$ per phase is $2\beta/p$.

SYNCHRONIZING POWER. The synchronizing power of any synchronous machine is a measure of its ability to keep in step with others in parallel with it, generators or motors. It is expressed in the rate of change of power with respect to the displacement angle β, i.e., total kilowatts (all phases) per electrical degree (A.I.E.E. Standards).

$$\text{Synchronizing power, } P_s = \frac{\text{Power input}}{\beta}$$

where $\beta = \sin^{-1}\dfrac{\text{Power input}}{E \times \text{short-circuit current}}$, very closely.

A high resistance between machines reduces the synchronizing power as it reduces the impressed voltage. A reactance is not so bad. Increasing the excitation increases the short-circuit current and increases the synchronizing power.

HUNTING: NATURAL PERIOD. The rotating part of every synchronous machine acts like a pendulum, tending to swing ahead and behind its normal synchronous position. The mass of the armature (and its flywheel) acts like the mass of the pendulum, and the torque of the machine, being proportional to the displacement (β), corresponds to a spring or gravity acting on a pendulum. Such a combination has an "electromechanical period" of its own, and if the frequency of this period is in tune with any other pulsating force in the system, such as engine impulses, "hunting" or "surging" may occur.

The A.I.E.E. Standards give the natural frequency of hunting of any synchronous machine as:

$$F = \frac{266{,}500}{N}\sqrt{\frac{P_s f}{WR^2}}$$

in which F = cycles per minute.
N = revolutions per minute.
P_s = synchronizing power.
f = frequency of supply, cycles per second.
W = total weight (pounds) of whole revolving part.
R = radius of gyration of W in feet.

The formula shows that the greater the flywheel effect WR the lower will be the frequency. The greater the short-circuit current or excitation the greater will be the synchronizing power and hence the higher the natural frequency. The frequency may be decreased by connecting reactance coils in series with the machine between the bus-bars and the terminals of the machine. If F_0 is the frequency of any other pulsating force in the system the danger of hunting is greatest when

$$F/F_0 = 1, 2, 3, 4, \text{etc.}$$

A tendency to hunt is damped by solid pole pieces, bridges between poles, or, best of all, a squirrel-cage winding in the pole faces.

MAXIMUM OUTPUT. As the current which would flow during maximum output of a synchronous motor is so great that it would burn up the windings in case this output should last more than a fraction of a second, the value of the maximum output is of theoretical interest only. In practice the maximum output (for a given voltage) is only reached under two conditions: (1) when, owing to extraneous causes, the line voltage decreases to a fractional value, the maximum output decreasing as the square of the voltage; (2) when, owing to hunting or pulsation, the flow of energy into and out of the machine reaches excessive values momentarily. In one of these swings the power may reach the value of the maximum output or exceed it and the machine shut down. Although the power of the machine drops off gradually after the point of maximum output has been reached, the motor is unstable in this region and is more than likely to shut down when the condition is reached.

STARTING TORQUE. Synchronous motors may be started either as hysteresis * or induction motors. In the former case the motor requires a high voltage and takes a small current, but as the torque is very slight this method is seldom used in practice. When starting as an induction motor a high armature reaction is desirable and a low leakage reactance. A squirrel-cage winding in the pole face must be provided, and as in an induction motor this squirrel-cage winding must have a cross-section approximating a certain value. If the cross-section is too large, the currents will be excessive and the starting torque not the best. If the cross-section is too small, the currents will be small and the starting torque not the best. The cross-section of the squirrel-cage winding may be roughly predetermined by treating the machine as an induction motor, but this method is not accurate because the construction of the field renders the calculation of the leakage reactance inaccurate. It is thus much better determined empirically.

During starting and acceleration the armature flux sweeps past the field poles at high speed and induces a high voltage in the field windings. To protect these windings it is customary to break them up into several sections which are kept separate during starting and closed in series by the "field break-up switch" when synchronism has been closely approached. Salient-pole synchronous motors, if especially designed for starting conditions, will give 110 per cent of rated torque on starting and a "pull-in" torque of 110 per cent, with 3 to 4 times rated current. Starting torques of 2 or 3 times rated may be obtained by any of three special features:

* A piece of iron in a rotating field has a torque produced on it due to the hysteresis and eddy currents set up in it. Such an arrangement may be called a "hysteresis" motor; an open-circuited field of a polyphase synchronous motor therefore forms a hysteresis motor.

(*a*) A friction clutch between rotor and load.

(*b*) The "super-synchronous" motor in which both the primary and the field are rotatable on bearings, the field is normally the rotor but in starting is held stationary by the load. The primary, when voltage is applied, starts free and comes up to synchronous speed. Then a friction brake is applied to the primary; this reduces its speed, exerts a strong torque on the rotor, starts the load, and brings it up to speed as the primary comes to rest. This type will give 300 per cent torque in starting with 300 per cent current.

(*c*) The synchronous motor with polyphase wound rotor. The rotor is like that of an induction motor. It starts as a true induction motor with proper resistance in the secondary and has the usual starting characteristics of this type of motor. When the rotor approaches synchronism it is first completely short-circuited and then a direct current is introduced through one phase in series with the other two in parallel. This gives the d-c excitation.

PULL-IN TORQUE. In addition to the starting or stationary torque the "pull-in" torque is important in a synchronous motor.

It is the torque which the motor can exert to pull the rotor (and its load) into exact synchronism from the induction motor speed which is slightly less than synchronism (1 to 5 per cent). The lower the final resistance of the secondary the less is the slip and hence the easier is synchronization. Salient-pole rotors synchronize more easily than round rotors and usually synchronize before the d-c field is established; round rotors usually require d-c excitation before they synchronize. A very high load drag or considerable flywheel effect in the load make synchronization difficult as they require a great pull-in torque.

ROTARY PHASE MODIFIERS OR ROTARY CONDENSERS. Synchronous motors are sometimes used to improve the power factor and reduce the line current of an installation of a number of induction motors. If a factory has an installation of 100 kva of induction motors having an average power factor of 71 per cent and taking I amperes, then by installing a synchronous motor of 100 kva rating, designed to be overexcited, the power available will be doubled and the line current increased only by 41 per cent or to 1.41 I. Such a machine is called a "rotary condenser," and if it is rated at 100 kva it may give 71 kw of power and 71 kva to balance the reactive effect of the inductive apparatus. Other relations may be obtained in accordance with the principle of vector combinations.

Let P_1 = true power taken by the induction motors, kilowatts.
Q_1 = reactive power taken by the induction motors, kilovolt-amperes.
$L = \sqrt{P_1^2 + Q_1^2}$ = total kilovolt-amperes of induction motors.
P_2 = true power taken by rotary condenser, kilowatts.
Q_2 = reactive power taken by rotary condenser, kilovolt-amperes.
$K = \sqrt{P_2^2 + Q_2^2}$ = total kilovolt-amperes of condenser.

Then
$$\text{Line kva} = \sqrt{(P_1 + P_2)^2 + (Q_2 - Q_1)^2}$$

12. TESTS OF SYNCHRONOUS MOTORS

Certain tests on synchronous motors are the same as those made on an a-c generator; the methods of carrying out such tests are described in the article on Alternating Current Generators. The first five of the following tests are of this character:

1. **Resistance of armature and field circuits both cold and hot.**
2. **Saturation curve at no load and under special circumstances at full load.**
3. **Core loss.**
4. **Short-circuit or synchronous impedance.**
5. **Insulation tests.**
6. **Phase Characteristics or V-Curves** at no load, full load, and any other specified load. The machine is operated as a motor with the specified load kept constant throughout the run. The voltage and frequency impressed upon the motor are also kept constant. The current in the field is varied from the minimum at which the motor will operate to the maximum (from $^1/_4$ normal to 1 $^1/_2$ normal) and the variation in current input to armature noted. Readings are taken of load, volts armature, amperes armature, and amperes field. A curve is plotted with amperes armature as ordinates, and amperes or ampere turns per pole in field as abscissas. This gives the characteristic V-curves of the synchronous motor (see Fig. 5). The point of minimum current input for each load is very clearly shown. At this point the power factor is unity. At lesser values of field current the armature current is lagging and the power factor poorer. At greater values of field current the armature current is leading. The point of minimum current occurs at a higher value

of field current for the greater loads because the field excitation must be increased with the load to overcome the armature reaction due to the load current.

Compounding Curve. The curve connecting the points of minimum armature current in the group of V-curves is called the compounding curve for unity power factor.

7. Starting Tests. A low voltage is impressed on the armature and gradually increased until the motor starts. The field circuit is open in two or more places and a high-potential voltmeter connected across one section to determine the voltage induced in the field spools by the rotating magnetic flux. The test is repeated for several different initial positions of the revolving part, and a record is made of the time required for the machine to reach synchronism. The time at which synchronous speed is reached may be determined by the fact that the induced voltage in the field becomes zero. Readings are taken of volts armature, amperes armature, initial position, maximum volts field, time to reach synchronism. See also paragraph on Starting, below.

8. Armature Phase Position. The phase position of the armature discussed previously may be measured, although the item is of only theoretical interest and not of commercial importance. A synchronous motor is supplied with power from a special a-c generator, and on the end of the shaft of each machine is placed a contact-making disk, as shown in Fig. 6.

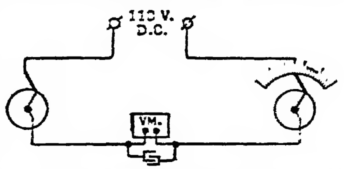

FIG. 6. Contact Method of Measuring Armature Phase Position

A voltmeter is connected in series with a source of direct current, the two disks, and the brushes pressing on the disks. The voltmeter reading is a maximum when the two brushes are in contact with the metal strips at the same time. The brush on the motor may be moved over a graduated scale or arc, so that its position may be varied and the actual angular movement measured. The brush on the generator remains stationary. As the load on the motor is increased it will be found necessary to move its brush in order to keep the voltmeter reading at its maximum value, and the angle β through which the brush has been moved for the change in load gives the phase position of the motor armature with respect to the generator armature. It will be found that the value of β is directly proportional to the load. The difference in phase of the electromotive forces in electrical degrees will be β multiplied by the number of pairs of poles of the motor. If hunting exists, the maximum angle of swing may be determined by moving the motor brush first one way as far as the effect may be noticed, and then in the other direction.

SPECIFICATIONS. Synchronous motors are rated in the same manner as synchronous generators, and the same heating limits and specifications apply. (See Alternating Current Generators.) It is customary to specify the value of the current taken by the motor in starting with no load other than the friction of its own bearings, or its own friction plus that of the machine to which it is connected, if it is part of a motor-generator set. It is also sometimes mentioned in the specifications that the motor will not hunt providing the total resistance drop between the generator and motor is less than some specified value (10 or 15 per cent).

13. INSTALLATION AND OPERATION

The precautions to be taken in installation are the same as for a-c generators (q.v.). Direct current must be provided for excitation. If a synchronous motor is operated on a polyphase system having unbalanced voltages it will take unequal currents in the different lines and tend to balance the voltages. These unequal currents, however, increase the heating somewhat for a given load.

STARTING. Provision must be made for a reduced voltage for starting the motor, either by means of taps on the transformers or by means of a starting compensator (q.v.). Large motors require two steps in starting, $^1/_3$ and $^2/_3$ of normal voltage. Small motors will start with one step at $^1/_2$ voltage. The field circuit is opened by the field "break-up" switch and a voltage applied to the armature. When the armature current has decreased from its large value at starting to a reasonable value the voltage is increased, step by step. When the motor has reached maximum speed the field is excited and the motor pulls into synchronism. The field current is then adjusted until the condition of minimum armature current is found or until the power-factor indicator records unity power factor. The load may then be applied.

If a synchronous motor is to be started often (several times a day) it is desirable to provide a special starting motor which brings the synchronous motor up to a speed a little above synchronism. Synchronizing must then be effected as in a-c generators. Such a

starting motor would require only about 30 per cent of the full-load current of the motor, and therefore have very little effect on the regulation of the system and not cause disturbance to the lights and other motors on the system. It usually requires less than a minute to bring a motor up to speed.

WEIGHTS. A standard line of synchronous motors for 60 cycles, 1200 rpm three-phase, 100 per cent power factor and for voltages up to 550 has weights (including base, pulley, exciter, and hand starter) approximately as follows:

Rating, hp	Weight in Pounds, Complete
25	1600
50	2500
100	3000
150	4000
200	4500

POLYPHASE INDUCTION MOTORS

An induction motor may be either single, two, or three phase. Single-phase induction motors are treated in another chapter (q.v.). The induction motor is essentially a polyphase transformer with the secondary free to move; the electric energy transferred to the secondary is transformed by this motion directly into mechanical energy.

14. DEFINITIONS AND PRINCIPLES OF OPERATION

Certain terms used in connection with the induction motor can best be defined by a brief statement of the principles underlying its operation.

Primary and Secondary. By the primary of an induction motor is meant that part which receives energy by direct connection to the source of electric energy; the other member is called the secondary.

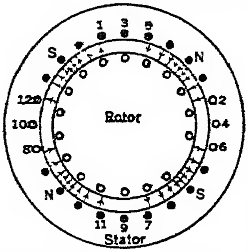

Fig. 1. Elementary Induction Motor

Stator and Rotor. That member of an induction motor which remains stationary, whether it be the primary or secondary, is called the "stator," and the revolving member is called the "rotor." In most machines the primary is the stator. A "squirrel-cage" rotor is one in which the conductors are straight bars of copper all connected together at each end of the rotor by copper rings.

Poles of an Induction Motor. In Fig. 1 is given a diagram of the primary winding of a two-phase four-pole induction motor. The small numbered circles represent the conductors forming the winding of one phase, the small black circles the conductors forming the winding of the second phase. The numbers opposite the circle give the order in which the current in phase 1 passes through the conductors, a cross indicating that the current goes down into the page and the open circles that the current is coming up.

The diagram is drawn to represent that instant at which the current in the second

phase is zero. At this instant the distribution of flux in the air gap will be roughly as indicated by the lines with arrows on them; that is, the flux will leave the stator iron in the two regions marked N and enter it in the two regions marked S. Consequently, the current in the winding of phase 1, which consists of 4 bands or groups of conductors, will produce 4 polar regions, or 4 poles, on the stator. As will be shown below, the combined effect of the two phase currents in the two windings is merely to cause a rotation of these polar regions. The " number of poles " is always equal to the number of bands of conductors into which the total winding of each phase is divided. The bands of conductors forming one phase usually overlap the bands of conductors forming the other phase, there being then two or more conductors per slot.

ROTATION OF MAGNETIC FLUX. In Fig. 1 is shown the distribution of flux in the gap when the current in phase 2 is zero; the curve marked A in Fig. 2 represents this same state of affairs, the cylindrical surface of the stator here being bent out into a plane, and the ordinates of the curve giving the value of the flux density in the gap at each point of this surface. The flux distribution is not a smooth curve as shown, but approximates such a curve.

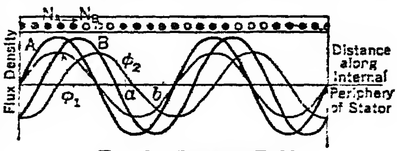

FIG. 2. Rotating Field

Next consider the case when the current in phase 1 has decreased to, say, 0.7 of its maximum value and the current in phase 2 has increased to 0.7 of its maximum value (this corresponds to 1/8 of the cycle). Then the flux distribution due to phase 1 remains in the same position as before but is reduced at each point of the gap to 0.7 of its maximum value, i.e., reduces to the curve marked ϕ_1. Similarly, the flux due to the current in phase 2 is similar in shape to the flux due to the current in phase 1, but its position is to the right of the latter by an amount equal to the width of one of the bands of conductors. The distribution of the flux due to the current in phase 2 is then as shown by the curve ϕ_2, the ordinates of which at the instant under consideration are 0.7 of their maximum values.

The resultant flux in the air gap at this instant is then the sum of the curves ϕ_1 and ϕ_2, namely the curve B. That is, the effect of the two fluxes due to the two phases is a resultant flux shifted forward, or moved around the gap, a distance equal to 1/8 the distance between successive north poles, but this resultant flux curve has the same shape and maximum value as before. This is strictly true only if the windings are distributed with absolute uniformity over the internal periphery of the stator. An extension of this analysis will show that the resultant flux remains constant in value at all times but travels around the air gap with a speed of

$$N = \frac{120f}{p} \text{ rpm}$$

where f is the frequency of the supply and p the number of poles.

This same result holds for a three-phase machine.

Synchronous Speed. The speed of rotation of the air-gap flux, namely the speed N given by the above formula, is called " synchronous " speed. At light loads the speed of the rotor is very nearly equal to this speed.

Slip. The slip of an induction motor is the ratio of the difference between the actual speed (N_1) of the rotor and synchronous speed (N) to the synchronous speed (N), i.e.,

$$s = \frac{N - N_1}{N}$$

The slip may be expressed as a fraction or as a percentage. The slip at standstill is unity; at no load it is very nearly zero. An induction motor driven at a speed higher than its synchronous speed has a negative slip; such is the case in an induction generator.

ELECTROMOTIVE FORCES IN SECONDARY. The emf's in the secondary of a polyphase induction motor are induced by the rotation of the flux produced by the currents in the primary windings, just as the emf's induced in the armature conductors of a generator are induced by the rotation of these conductors in the magnetic field set up by the field winding. In the generator only the conductors move, the field being stationary; but in the induction motor both the field and conductors move. In either case it is the *relative* motion of the field and conductors which determines the emf induced.

Let v be the linear speed at which the field moves, and let v_1 be the linear speed of the rotor conductors, and B the flux density at any particular conductor C at any instant. Then the emf induced in this conductor at this instant is $B(v - v_1)l = Blsv$, where s is the slip and l is the length of the conductor (see Section 3, Art. 49). The rotor emf is therefore proportional to the slip. As the rotor turns, the conductor C moves slower

than the rotating flux, and the state of affairs is just the same as if the flux remained at rest and the conductor moved through the field in the gap at a speed of $v - v_1 = sv$. Hence the emf induced in each rotor conductor is alternating, since the flux which it cuts varies from a positive maximum to a negative maximum, and a consideration of the relative speed of the conductor and the flux will show that the frequency of this induced emf is the frequency in the primary multiplied by the slip.

That is, the secondary electromotive force is proportional to the slip and has a frequency equal to the product of the slip and the frequency in the primary.

SECONDARY CURRENT AND TORQUE. The current set up in each rotor conductor by this emf will be practically in phase with this emf, since the rotor conductors have but a small reactance, particularly when the rotor is revolving at a speed near synchronism. Hence the current in any chosen rotor conductor at any instant is proportional to the emf in this conductor at that instant, which in turn is proportional to the flux density at this conductor at this instant. Since the force produced by a magnetic field on a conductor is equal to the product of the flux density by the current by the length of the conductor, the force acting at any instant on any rotor conductor will then be equal to

$$f = Bli = Bl\left(\frac{Blsv}{r}\right) = \frac{B^2 l^2 sv}{r}$$

where r is the resistance of the conductor. Since the current and the flux density both change signs at the same time (being in phase), the direction of this force will always be in the same direction and will consequently drive the rotor against whatever opposing force may exist.

Not only is the force on each conductor always in the same direction, but the *total* force acting on *all* the conductors is practically constant for a given value of the slip. Consider any two rotor conductors which are a distance apart equal to 1/4 the distance measured along the periphery of the rotor between successive north poles, for example, at a and b in Fig. 2. Then, assuming a sine-wave distribution of flux in the air gap, and calling B_m the maximum flux density, the flux density at a is $B_a = B_m \sin x$ and the flux density at b is $B_b = B_m \cos x$, where x is a function of the distance measured from some fixed point in the air gap. Then the total force on the two conductors at a and b is

$$\frac{l^2 svB_m^2}{r}(\sin^2 x + \cos^2 x) = \frac{l^2 svB_m^2}{r}$$

and is therefore constant, since B_m is a constant. Similarly for any other two conductors this same distance apart. Hence the total force on all the conductors is constant. On any practical machine the flux distribution is not an exact sine wave, and there is a slight pulsation in the total force, and therefore in the torque, but this pulsation is extremely small.

MAGNETIZING CURRENT. The currents set up in the secondary of an induction motor produce a rotating flux, which travels with the same speed with respect to the primary and in the same direction as the flux set up by the current in the primary, but the direction of this secondary flux at any point in the air gap is opposite to the direction of the primary flux. Hence the resultant flux when there is current in the secondary is equal to the difference of these two fluxes, and this difference remains practically constant irrespective of the secondary currents, just as the resultant flux in a transformer is practically independent of the secondary current. The primary current which would be necessary to produce this *resultant* flux is called the "magnetizing" current, and is very nearly equal to the current in the primary when the motor is running without load, in which case the current in the secondary is extremely small.

15. METHODS OF RATING

The Standardization Rules of the A.I.E.E. recommend that the rating of an induction motor should be the load in horsepower which it will deliver continuously at the shaft with a maximum rise in temperature of any part not exceeding 50 deg cent by thermometer.

Continuous Rating. The load (mechanical horsepower) which can be carried for an unrestricted period of time without exceeding any of the limitations as to temperature rise, etc., as established by the American Standards Association (Publication C50).

Short-time Rating. The load which can be carried for the time specified in the rating without exceeding these limitations.

In the absence of any specification as to the kind of rating the continuous rating is implied.

STARTING AND BREAK-DOWN TORQUE. In addition to the ability to carry its rated load without excessive heating and with reasonable constants, such as efficiency,

power factor, and slip, it is advisable to make sure that the motor is able to start such loads as must be brought up to speed with the motor, as good starting ability in an induction motor involves certain complications and expenses. This subject is treated at length in Art. 19, Methods of Starting. Another important point is that the motor should be able to carry momentary overloads without "breaking down" as it is called, which means gradually decreasing in speed to a standstill when the load is excessive. To be sure of this qualification we must know the maximum output of the motor, which should be at least 50 per cent greater than the rated output.

VOLTAGE. Motors may be wound for any voltage up to 13,000, but the great majority and all the small motors are wound for voltages of 110, 220, or 440 volts between lines.

FREQUENCY AND SPEED. Induction motors may be built for any frequency. The higher frequencies are satisfactory in those cases where the load never exceeds normal conditions. Lower frequencies, such as 25, are more favorable where frequent overloads are met with or large starting torques are required.

The speed of the rotor of an induction motor at normal loads approaches within 5 to 10 per cent of the synchronous speed. The synchronous speed is fixed by the frequency of the system and the number of poles of the winding so that for a given frequency of the supply circuit only certain speeds are available. Thus for 60 cycles we have

3600 for 2 poles; 1200 for 6 poles;
1800 for 4 poles; 900 for 8 poles, etc.

PHASE CONNECTIONS. Two-phase or quarter-phase motors are usually wound with independent phase windings. Three-phase motors are connected in Y or Δ, depending upon the convenience of the designing engineer.

In a single-phase and two-phase motor the voltage and current per phase are the same as the voltage between lines and current in line; in a Y-connected three-phase motor the current per phase is equal to the line current, and the voltage per phase is equal to the line voltage divided by $\sqrt{3}$; in a Δ-connected three-phase motor the current per phase is equal to the line current divided by $\sqrt{3}$, and the voltage per phase is equal to the line voltage.

CURRENTS TAKEN BY MOTORS.

Let P_0 = horsepower output.
I = current in each line.
ϵ = efficiency as a decimal fraction.
$\cos\phi$ = power factor as a decimal fraction.
E = voltage between lines (between one outside wire and the middle wire for three-wire two-phase line).

Then for

$$\text{Two phase: } I = \frac{373\,P_0}{\epsilon E \cos\phi}$$

$$\text{Three phase: } I = \frac{431\,P_0}{\epsilon E \cos\phi}$$

Usual efficiencies and power factors at full rated load for polyphase motors are as follows:

Table 1. Power Factors and Efficiencies

Horsepower	25 Cycles		60 Cycles	
	Efficiency	Power factor	Efficiency	Power factor
1	0.79	0.78	0.78	0.78
5	0.85	0.88	0.82	0.88
20	0.88	0.91	0.84	0.91
50	0.90	0.92	0.87	0.92
100	0.905	0.925	0.89	0.92
200	0.91	0.925	0.905	0.92

16. DESIGN

The methods of calculating two-phase and three-phase motors are practically the same. Most induction motors on single-phase circuits are made with polyphase windings, as the extra winding is necessary in starting.

The factors which must be considered in the design of an induction motor are the same

as those considered for a synchronous generator with the addition of the power factor. It is desirable to have a high power factor, but a high power factor requires a generous use of material, a small air gap, and a careful arrangement of windings. A high power factor at light load requires a small magnetizing current, and a high power factor at overloads requires a low value of leakage flux.

A small value of magnetizing current is obtained by using a small air gap and a large value of diameter per pole.

A low value of leakage flux is obtained by using a large value of diameter per pole and by subdividing the windings in a large number of slots.

GENERAL PROPORTIONS. In the discussion below the following symbols are employed:

E = volts per phase.
I = full-load current per phase.
I_m = magnetizing current per phase.
D = diameter of armature, inches.
L = length of armature core, inches.
L_1 = length of iron = (L − air ducts), inches.
l = effective length of iron, inches = 0.9 L_1.
p = number of poles.
f = frequency in cycles per second.
g = length of gap, inches.
B = average flux density in air gap, maxwells per square inch.
Φ = flux per pole, maxwells.
S = turns in series per phase.
N = revolutions per minute.
V = peripheral speed in feet per minute.
σ = ampere-conductors per inch of periphery.

General equation: $$\text{Kva input} = \frac{\sigma B V D L_1 k_2 k_3}{144 \times 10^9}$$

This is the same as for polyphase generators (see Art. 2, eq. 1) except that ρ is unity and L_1 the actual length of iron must be used for accuracy as there is very little spreading of the flux in the air gap. σ has values as given in Table 2. Usual values of B are 25,000 in 60-cycle motors and 30,000 in 25-cycle motors. V is determined by the mechanical construction chosen and usually is between 4000 and 6000 fpm. k_2 and k_3 are the winding constants as given on p. 9–08. L_1 is usually the desired unknown quantity. With $^1/_2$-in. ducts spaced 2.5 in. the relation is $L = (L_1 + {}^1/_2\, n)$, where n is the number of air ducts.

Table 2. Data on Induction Motors

Diameter, inches	Slots, number	Depth of Slots, inches	Gap, Radial, inches	Ampere-conductors per Inch
10	48–60	1.0 –1.4	0.02–0.03	350
20	60–90	1.25–1.8	0.03–0.04	500
30	72–120	1.5 –2.0	0.04–0.05	600
50	168–192	1.8 –2.12	0.06	850
100	300–420	3.0 –4.0	0.10	1000
150	260–450	3.5 –5.0	0.15	1200

The flux per pole is $\Phi = \dfrac{\pi BDL}{p}$, and the number of turns in series per phase is

$$S = \frac{\pi D \sigma}{2I \times \text{Phases}}.$$

The total number of "effective conductors" around the whole periphery of the primary is $Z = 2S \times$ Phases. These may be subdivided by the use of parallel conductors or parallel paths so that the real number of conductors is 2, 4, 6, etc., times this quantity. The winding of an induction motor is of the same general construction as is used in a-c generators (page 9–05). The multiple or lap winding is always used with two or four coil-sides per slot and two, three, or four slots per pole per phase. Thus several consecutively placed coils are connected in series in one phase belt, which may be connected either in series or multiple with the phase belts under other poles. Each coil may have as many turns in series as necessary for the voltage.

The three phases may be connected either in Y or in delta to suit the exigencies of the design. Fractional pitch is quite generally used to reduce the leakage reactance and the length of the end-connections, particularly in machines with a large diameter per pole, such as 25-cycle motors and high-speed machines with a small number of poles. A pitch of two-thirds is common in 25-cycle motors and five-sixths in 60-cycle machines.

The size of each conductor depends upon the current to be carried and the current density, which may be used as determined by heating. For a rise of 50 deg cent the values of current density given in Table 3 are usual in open motors having self-ventilation, like most industrial motors.

Table 3. Current Densities

Size of Motor	Voltage	Amperes per Sq In.
Small..........	Low...........	3000
Small..........	High...........	2000
Large..........	Low...........	2000
Large..........	High...........	1600
Large..........	Above 6000 ..	1000

In the United States the practice is to use open slots in the primary, the slots having a depth about four times the width and containing two coil-sides. In Europe, with lower labor costs, partly closed slots with overhung teeth are used extensively. In all cases the secondary slots are almost closed at the face and four-coil sides per slot are used for a definite winding to which external resistance is to be connected for starting, while one bar per slot is used for a squirrel-cage winding. These bars are well connected electrically to a ring at each end, sometimes of copper, sometimes of brass.

The size of the slots is determined by the size and arrangement of the conductors and the insulation, which consists of insulation on the individual conductors and on the coils, and in some cases of an insulating lining to the slots. This insulation occupies space as given in Table 4, the dimensions being total, on both sides of the conductors and coils, and also allows for the wedge which holds the coils in the slot. The width of open slots is from one-half to two-thirds of the slot pitch along the gap. The width of closed slots may be slightly greater than this.

Table 4. Insulation Allowances

Type of Slot	Voltage	Coil-sides per Slot	Allowance for Insulation	
			Vertical	Horizontal
			in.	in.
Straight......	500	2	0.30	0.08
Straight......	2200	2	0.45	0.15
Straight......	6000	2	0.65	0.25
Overhung....	500	4	0.40	0.15
Overhung....	2200	4	0.50	0.20

FLUX PER POLE.
$$\Phi = \frac{E \times 10^8}{4.44 fSk}$$

where k is the combined distribution constant of the winding as in Table 5.

Table 5. Distribution Constant k

Two Phase					Three Phase				
Slots per Pole	Per Cent Winding Pitch				Slots per Pole	Per Cent Winding Pitch			
	100	75	67	50		100	75	67	50
	k	k	k	k		k	k	k	k
2	1.00	....	....	0.71	3	1.00	....	0.87	....
4	0.93	0.85	....	0.66	6	0.97	....	0.84	0.69
6	0.91	....	0.79	0.64	9	0.96	....	0.83	0.68
8	0.905	0.84	....	0.64	12	0.96	0.89	0.83	0.68
12	0.90	0.836	0.78	0.63	18	0.958	0.885	0.83	0.68
Many	0.90	0.833	0.78	0.63	Many	0.958	0.885	0.83	0.68

PHASE CONNECTION. Whether a motor shall be delta or Y connected depends upon such minor details as the convenience of arranging the conductors in the slots. For instance, if for 110 volts and delta connection a desirable flux value and number of conductors would require 7 conductors per slot, a Y connection having 64 volts per phase and 4 conductors per slot could be substituted and would give a practicable winding; 64 volts per phase in Y connection gives 110 volts between lines.

EXCITING CURRENT. This current is made up of two components: the "magnetizing current" which lags the impressed voltage by 90 deg, and a component in phase with the impressed voltage which supplies the core loss. The "no load" or "running light" current consists of the magnetizing current and a small component to supply the friction loss. The magnetizing current is much the largest component, so that it is frequently stated that the running light current is the magnetizing current.

The distributed primary winding, which is the seat of the mmf, gives a peaked wave

shape of mmf in the teeth and gap which, with three phases and full pitch, takes the form shown at a in Fig. 3 at one instant and then one-twelfth cycle later takes the form shown at b, and changes from one to the other of these every twelfth of a cycle. At the same time the wave moves one-twelfth of a pair of poles along the air gap, the change from a to b being gradual. The maximum value varies between 1.72 and 1.5 times the average value with a mean of 1.61. If there were no saturation in the iron the flux would do the same but, owing to saturation in the teeth under the peak, the real flux wave is not as peaked, so that a reasonable value for the ratio of the maximum to the average flux density is from 1.57 to 1.5 and is usually taken at 1.57 although with extremely high densities in the teeth the ratio is 1.5. Customary values for the magnetic densities in the various parts are given in Table 6.

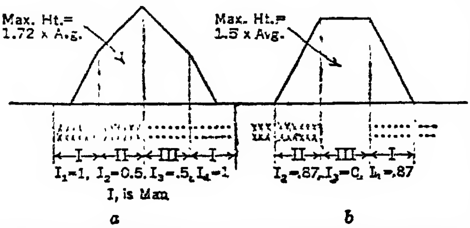

Fig. 3. Distribution of the Mmf of the Primary for the Two Limiting Conditions. Six Slots per Pole per Phase, Full Pitch

Table 6. Usual Maximum Flux Densities

	25 Cycles	60 Cycles
Stator core..........	70,000	50,000
Stator teeth.........	90,000	70,000
Air gap.............	48,000	40,000
Rotor teeth.........	80,000	60,000
Rotor core	90,000	80,000

MAGNETIZING CURRENT. The magnetizing current is calculated by determining the flux density in each part of the magnetic circuit and the ampere turns required for each part. This is most easily done by means of the following tabulation:

Magnetic Densities and Mmf's

(For dimensions refer to Fig. 4)

Part	Flux per Pole	Area	B_{max}	A.T. per Inch	Length Path	Total A.T.
Stator core........	$\phi/2$	$h_1 \times l$	$1 \times B_{avg}$	......	$\dfrac{\pi D_1}{2 \times \text{poles}}$	......
Stator teeth.......	ϕ	$t_0 \times l \times \dfrac{\text{slots}}{\text{poles}}$	$1.57 \times B_{avg}$	......	n_1	......
Air gap...........	ϕ	See below	$1.57 \times B_{avg}$	......	$C_1 C_3 g$	......
Rotor teeth........	ϕ	$t_3 \times l \times \dfrac{\text{slots}}{\text{poles}}$	$1.57 \times B_{avg}$	......	n_2	......
Rotor core.........	$\phi/2$	$h_2 \times l$	$1 \times B_{avg}$	......	$\dfrac{\pi D_2}{2 \times \text{poles}}$	......
					Total.....	....

Stator Core or Yoke. The flux divides in the core, one-half going each way. The maximum and average densities are practically the same and equal to ($\phi/2$ divided by the radial depth h_1 times the effective length l). The material is laminated steel of high permeability. The ampere-turns per inch length of path are obtained from a magnetization curve of the steel; see Magnetic Materials, Sect. 2. The length of path is indeterminate but closely approximates one-half of the pole pitch measured on the circle of diameter D_1. By multiplying the ampere-turns per inch obtained from the magnetization curve by the length of path, the ampere-turns required to send the flux through this path are obtained.

Stator Teeth. The average density in the teeth is first obtained. The effective area of one tooth is the area one-third the distance from the face to the root of the tooth as shown at t_0. This gives the average magnetizing force rather than the average density. The total cross-section of the path in the teeth is therefore $t_0 \times l \times$ (the number of teeth per pole). Owing to the peaked or sinusoidal space distribution of the flux the maximum density in the teeth is 1.57 times the average density. The ampere-turns required depend upon the maximum density. From the proper curve determine the ampere-turns per inch necessary to establish this density, and, by multiplying this quantity by the distance n_1 in inches, the ampere-turns for the stator teeth are found.

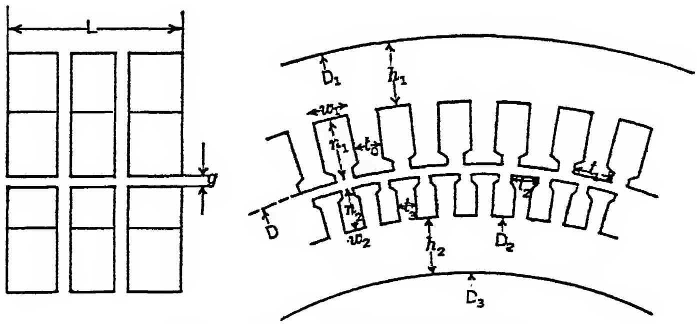

FIG. 4. Cross-section of Magnetic Circuit

The air gap in induction motors is very short, hence the flux is very definitely bunched at the faces of the teeth and this phenomenon assumes more importance than in any other type of machine. This is evaluated by the "Carter coefficient" which is explained on page 8–09 under D-c Generators.

Since, in an induction motor, there are slots in both the stator and rotor, there are two coefficients, C_1 and C_2. C_1 is for the stator and is based upon the stator slot opening and the stator slots per pole. C_2 is for the rotor and is based upon these characteristics of the rotor. The area of path is $\frac{\pi D L_1}{\text{Poles}}$, the maximum space density is $\frac{1.57\,\Phi}{\text{Gap area}}$. The ampere-turns per inch are max density $\times$ 0.313. The equivalent gap length is $C_1 C_2 g$, and the ampere-turns for the air gap are $1.57B \times 0.313\, C_1 C_2 g$.

Rotor Teeth. The calculation of the ampere-turns for the rotor teeth follows the same method as the calculation for the stator teeth.

Rotor Core. The same as for the stator core.

In a three-phase machine the magnetization is produced by the combined effects of the three windings. At the instant shown at a the magnetic density is a maximum, the current in one phase is a maximum, and the total mmf of the three windings is

$$\sqrt{2}I\,S + \tfrac{1}{2}\sqrt{2}I\,S + \tfrac{1}{2}\sqrt{2}I\,S = 2\sqrt{2}SI$$

where I is the effective value of the magnetizing current. Hence the magnetizing current in a three-phase machine is:

$$I = \frac{(\text{Ampere-turns per pole}) \times \text{Poles}}{2\sqrt{2}S \times k}$$

where k allows for the effect of fractional pitch and form factor as in Table 5.

Similarly for a two-phase machine:

$$I = \frac{(\text{Ampere-turns per pole}) \times \text{Poles}}{\sqrt{2}S \times k}$$

The form of the magnetizing current is not a true sine wave because of saturation and hysteresis but it is much nearer to a sine wave than the magnetizing current of a transformer since the motor has a considerable air gap in its magnetic circuit.

RESISTANCE PER PHASE OF PRIMARY WINDING. The resistance to direct current, or ohmic resistance, is given by the formula

$$r_1 = \frac{0.01\, S \times (\text{Mean length of turn})}{12{,}000\, an},$$

where S = turns in series per phase.
a = cross-section of one conductor in square inches.
n = number of conductors or circuits in parallel.

0.01 is the resistance at 75 deg cent of a conductor 1000 ft long and 1 sq in. cross-section. The mean length of turn is approximately (see Fig. 4)

$$2L + 10\frac{D}{p} \times (\text{Pitch as a fraction}) \qquad \text{inches}$$

Owing to the eddy currents set up in the primary conductors by the total flux and to eddy currents set up in the core by the leakage flux, the "effective" resistance of the primary winding is about 15 per cent greater than the value calculated by the above formula.

RESISTANCE PER PHASE OF SECONDARY WINDING. In a wound rotor the resistance per phase is found in the same manner as the resistance per phase of the stator winding. The secondary resistance reduced to primary is then equal to

$$\left(\frac{\text{Number primary turns per phase}}{\text{Number secondary turns per phase}}\right)^2 \times (\text{Actual effective secondary resistance}),$$

when the secondary has the same number of phases as the primary.

Squirrel-cage Secondary. The effective resistance of a squirrel-cage winding is best calculated on the assumption of equal ampere-turns in primary and secondary at rated load and determining the losses in the secondary for any given current in the primary.

$$c_1 = \text{Effective conductors per primary slot} = \frac{\text{Actual conductors}}{\text{Parallel circuits}}$$

$$\text{Ampere conductors per secondary slot} = \text{Rated primary current} \times c_1 \times \frac{\text{Primary slots}}{\text{Secondary slots}}$$

$$\text{Current density in secondary bars} = \frac{\text{Ampere conductors}}{\text{Area one bar}}$$

$$\text{Watts lost in all bars} = 0.825\ 10^{-6}\ (\text{Volume of bars})\ (\text{Amperes per square inch})^2$$

$$\text{Area of bars per pole} = (\text{Area one bar})\ (\text{Number of bars per pole})$$

$$\text{Current density in rings} = \frac{(\text{Current density in bars})\ (\text{Area bars per pole})}{4(\text{Area of one ring})}$$

$$\text{Watts lost in rings} = 0.825 \times 10^{-6}\ (\text{Volume of both rings})\ (\text{Density in rings})^2$$

The loss in watts in 1 cu in. of copper at 75 deg cent and at 1000 amp per sq in. is 0.825. For other metals this is proportional to the relative resistivity.

Resistance at 75 deg cent of secondary in terms of the primary for a three-phase motor

$$r_2 = \frac{\text{Total loss}}{3(\text{Rated primary current})^2}$$

For a two-phase motor the factor 2 takes the place of the 3 in this denominator.

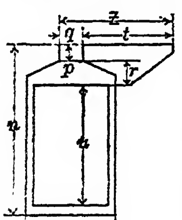

Fig. 5. Slot Dimensions

LEAKAGE REACTANCE. When the motor is loaded the currents in the secondary set up a counter mmf which causes part of the flux to pass along the air gap instead of into the secondary core. This flux does not interlink both members and is therefore a leakage or useless flux. It is proportional to the load currents and to the permeance of this path. As the greater portion of the path is in the air and is of high reluctance therefore that part of the path in the iron may be neglected. The flux in both the primary and secondary must be calculated.

There are three leakage flux paths to be considered in both primary and secondary. Referring to Fig. 5 the equivalent permeances or flux per ampere conductor are:

$$P_s = 3.2L\left(\frac{u_1}{3w_1} + \frac{2r_1}{w_1 + q_1} + \frac{p_1}{q_1}\right)$$

$$P_t = 3.2L\left(\frac{t_2 - q_1}{6g}\right)$$

$$P_c = 0.59 s_1\, l_c \log_{10} \frac{2l_c}{v_c} \text{ for a double layer winding}$$

$$P_1 = P_s + P_t + P_c$$

Primary leakage reactance per phase

$$x_1 = 2\,\pi f p s_1\, c_1^2\, P_1\, k\, 10^{-8} \text{ ohm}$$

Secondary leakage reactance per phase in terms of the primary winding:

$$x_2 = 2\,\pi f p s_2\, c_2^2\, P_2\, k\, 10^{-8} \times \left(\frac{c_1 s_1}{c_2 s_2}\right)^2$$

where g = length of gap in inches.
l_c = length of end connections at one end, in inches.

V_c = perimeter of a band of end connections per pole per phase, in inches.
c_1 and c_2 = the effective conductors per slot (see above).
s_1 and s_2 = the slots per pole per phase.
f = frequency.
L = total length.
k = winding distribution constant (see above).
P_1 and P_2 are for primary and secondary windings, respectively.

LOSSES IN INDUCTION MOTOR. The losses in an induction motor are:

Core loss.
Friction, bearing, and windage.
Primary copper loss.
Secondary copper loss.

The first two of these are approximately constant for all loads, and the last two vary as the square of the current per phase.

Core Loss. The distribution of the magnetic flux in an induction motor is quite irregular both in the core and in the teeth. The losses are therefore greater and their calculation more involved than in machines having uniform density in each part. In the primary the frequency of the passage of the secondary teeth introduces pulsations which increase the losses. In the secondary the frequency, being proportional to the slip, is so low that the core loss is negligible.

In order to avoid too lengthy and complex calculations use is made of empirical constants, by which the easily calculated losses are multiplied to derive the practical loss. The total loss consists of hysteresis and eddy-current loss in the primary core and primary teeth. The loss in watts per cubic inch for one cycle per second at any magnetic density is found by the curves given in the article on Magnetic Materials.

The losses are then calculated as follows:

Hysteresis Loss:
In primary core $= k_h C_1 f V_c$ watts,
In primary teeth $= k_h C_2 f V_t$ watts.
Eddy-current Loss:
In primary core $= k_e C_3 f^2 V_c$ watts,
In primary teeth $= k_e C_4 f^2 V_t$ watts,

where V = volume in cubic inches; f = frequency; k_h = empirical constant, 1 to 1.5; k_e = empirical constant, 3 to 4; C_1, C_2 = hysteresis loss per cubic inch for one cycle per second; C_3, C_4 = eddy-current loss per cubic inch for one cycle per second. η is usually 0.002 and $\epsilon = 0.0001$.

The higher values of k_h and k_e are to be used where open slots are used and where the frequency of the passage of the secondary teeth past one primary tooth is high. The core loss is the sum of all the above losses.

Friction and Windage Loss varies greatly with the style of motor and form of structure bearings, etc. The loss is made up of bearing friction and wind friction. The latter may be large purposely, as the motor may be designed with fan blades in order to circulate the air for the purpose of keeping the motor cool by ventilation. As each manufacturer has a formula which will calculate the friction loss correctly for machines built according to a particular plan, no general formula can be assumed. The nearest approach to an estimate is obtained from the percentage given in the table below.

Primary and Secondary Copper Losses. The calculation of the effective resistances of the primary and secondary windings is given above. The primary or secondary copper loss is equal to the product of the number of phases, the effective primary or secondary resistance per phase, and the square of the current per phase. The total copper loss is the sum of the primary and secondary copper losses.

POWER FACTOR. The power factor ($\cos \phi$) of an induction motor for a given current input (I) may be calculated roughly as follows:

Let $\frac{I_m}{I} + \frac{IX}{E} = a$. Then

$$\text{Power factor} = \frac{1}{\sqrt{1 + a^2}}$$

where I_m = magnetizing current per phase.
I = total current per phase.
$X = (x_1 + x_2)$ = total reactance per phase, the secondary reactance x_2 being reduced to the primary turns.
E = voltage per phase.

For a more exact formula for power factor and for the usual values of the power factor at rated load, see below.

EFFICIENCY. The efficiency (as a fraction) for a given current input is

$$\epsilon = 1 - \frac{F + C + m(r_1 + r_2)I^2}{mEI \cos \varphi}$$

where F = friction loss, in watts.
C = total core-loss, in watts.
m = number of phases.
r_1 = effective primary resistance per phase.
r_2 = effective secondary resistance per phase reduced to primary.
E = voltage per phase.
I = current per phase.
$\cos \phi$ = power factor.

The corresponding horsepower output is then

$$P_0 = \frac{\epsilon mEI \cos \phi}{746} \text{ horsepower}$$

Usual values of the efficiency are given above in the paragraph, Currents Taken by Motors. Usual values of the component losses for 60-cycle motors are given in the following table.

In 25-cycle motors the exciting current is usually greater than in 60-cycle motors and the IX drop less. Thus the power factor will be lower at light load and higher at overloads than in 60-cycle motors.

Table 7. Induction Motor Losses

Rating, hp	$\frac{I_m}{I}$	$\frac{XI}{E}$	$\frac{\text{Friction loss}}{\text{Input}}$	$\frac{\text{Core loss}}{\text{Input}}$	$\frac{r_1 I}{E}$	$\frac{r_2 I}{E}$
1	0.45	0.20	0.06	0.05	0.05	0.05
5	0.35	0.14	0.03	0.04	0.04	0.04
20	0.30	0.13	0.02	0.035	0.03	0.035
50	0.27	0.11	0.015	0.03	0.025	0.03
100	0.26	0.11	0.015	0.03	0.025	0.025
200	0.25	0.11	0.015	0.03	0.025	0.02

The efficiency of 60-cycle motors naturally tends to be higher than of 25-cycle motors. This quality is usually sacrificed by economizing in material and making the 60-cycle motors lighter and cheaper but of about the same efficiency as the 25-cycle motors.

Maximum Efficiency and Power Factor. Since induction motors frequently operate on an intermittent or variable load, it is desirable that the efficiency and power factor be high at fractional loads. It is therefore quite usual to design the motors so that the maximum efficiency comes at $^3/_4$ load and maximum power factor at less than full load. This is accomplished with regard to efficiency by making the core loss and friction small (the core loss is made small by using low flux densities) and with regard to power factor by making the magnetizing current small by using a small air gap.

SLIP AND SPEED. The slip for any given current is approximately

$$s = \frac{r_2 I}{E}$$

where the symbols are defined in the preceding paragraph.

The synchronous speed is

$$N = \frac{120 f}{p} \text{ rpm}$$

where f is the frequency of the supply and p the number of poles. The actual speed of the motor is then

$$N_1 = (1 - s) N$$

VALUES OF OTHER CHARACTERISTICS. The energy component of the no-load current is

$$I_e = \frac{(\text{Total core loss}) + (\text{Total friction loss})}{mE}$$

where m is the number of phases and E the volts per phase.

The total no-load current per phase is then

$$I_{00} = \sqrt{I_e^2 + I_m^2}$$

where I_m is the magnetizing current per phase.

The impedance per phase at standstill ("short-circuit" impedance) is

$$Z = \sqrt{(r_1 + r_2)^2 + (x_1 + x_2)^2}$$

where r_1 and r_2 are the effective values of the primary and secondary resistances per phase, the latter being reduced to primary turns, and x_1 and x_2 the primary and secondary reactances per phase, the latter being reduced to primary turns.

The current per phase at standstill ("short-circuit" current) is

$$I_s = \frac{E}{Z}$$

The starting torque in pounds at 1-ft radius is

$$T_s = \frac{7.06\, m r_2 E^2}{N Z^2}$$

where m, r_2, E, and Z are as defined above, and N is the synchronous speed in revolutions per minute.

The slip at maximum output is

$$s_m = \frac{r_2}{r_2 + Z}$$

The maximum output in watts is

$$P_m = \frac{0.5\, mE^2}{1.3\,(r_1 + r_2) + Z} \text{ watts}$$

This should be from 1.5 to 3 times the rating of the motor. A 25-cycle motor usually has a greater maximum output or overload capacity than a 60-cycle motor.

HEATING. Since in most induction motors the primary member is subject to both a core loss and a copper loss and is stationary, the heating of this member is very important. As the secondary contains only a copper loss and is usually revolving, its rise in temperature is generally much less than that of the primary.

The problem therefore consists of analyzing the flow of heat and drop in thermal potential in the primary as the energy lost in the windings flows to the iron of the core through the insulation in the slots and to the air around the projecting end connections. The core itself is maintained at a temperature above the air by the core loss. It is therefore necessary to calculate first the rise in temperature of the iron of the core caused by the core loss and that portion of the copper loss which is conducted to the core through the slot insulation. It is then necessary to calculate the rise in temperature of the copper above the iron and above the air around the end connections.

The laws for the flow of heat and difference in temperature in the primary of an induction motor are the same as in the armature of a d-c machine. The principal uncertainty is the velocity of the cooling air as it is induced by the intentional irregularities of the surface of the rotor which form small fan blades. However, the analysis given for d-c generators (page 8–19) is also used for induction motors.

17. TESTING OF INDUCTION MOTORS

(See also Standardization Rules of A.I.E.E.) Induction motors may be given either an "input-output" test at load under working conditions, from which the efficiency and power factor may be determined, or the motor may be given a no-load excitation and no-load short-circuit test, from which all the characteristics may be calculated. The latter method requires very little power and is preferable for large motors where it would be expensive to supply power and inconvenient to dissipate the energy.

EXCITATION TEST. In this test the machine is operated without load at constant frequency with the voltage varied through a range from 30 per cent above rated value down to as low a voltage as will cause the machine to rotate. The current in each phase is noted, and by means of two wattmeters the power required is noted. This test is sometimes also made with the machine operating single phase for the purpose of checking the core loss. The curves are plotted with voltage as abscissas and amperes and watts as ordinates. At very low voltages the core loss is negligible and therefore the watts input may be taken as friction loss. Around normal voltage the real core loss may be determined by subtracting from the input the small copper and the friction loss.

SHORT-CIRCUIT IMPEDANCE TEST. In this test the starting resistance, if there is any, is short-circuited and the armature is blocked to prevent rotation. A low voltage

is applied to the primary until the ammeter in the primary circuit shows a current of from 1 to 1.5 times the full-load value. Two watt-meters are used to read the power input. As the leakage flux, and hence the reactance, varies with the relative position of the rotor and stator teeth, it is customary to take readings with the rotor in several positions. Sometimes the rotor is allowed to revolve very slowly at, say, 2 to 3 rpm. From this test the impedance (Z) of the machine is obtained by dividing the volts per phase by the current per phase; the combined effective resistance (R) of primary and secondary is found by dividing the watts input per phase by the square of the current per phase. This latter is the effective value of the resistance, since the watts input includes all losses due to eddy currents. From these values the total reactance (primary and secondary) of the motor is $X = \sqrt{Z^2 - R^2}$. With the results of the two preceding tests and the measured resistances of the two members, the characteristics of the motor may be calculated either by the Steinmetz Method or the Circle Diagram. (See below under Calculation of Performance.)

STATIONARY TORQUE TEST (Fig. 6). This test may be made at the same time the impedance test is made; it consists in the measurement of the torque of the motor by means of a brake arm and spring balance. When the current of the machine has been adjusted to a suitable value the brake arm (to which a known weight has been attached to overcome bearing friction) and the spring balance are allowed to move downward through a small arc, during which the spring balance will register a pull (P_1) equal to torque (T) plus the weight (W) minus the friction (F), that is, $P_1 = T + W - F$. The spring balance and brake arm are then raised against the torque through the same small arc and the spring balance will then register a pull (P_2) equal to the torque plus the weight plus the friction, that is, $P_2 = T + W + F$. From these two readings the friction can be eliminated and the actual torque of the armature on the shaft is determined. This should be done at two or three equally spaced positions of the rotor, as the torque varies considerably with the position. The corrected torque of the machine is found by solving the two equations for T and multiplying T by the lever arm of the brake in feet; this gives the torque in pounds at 1-ft radius.

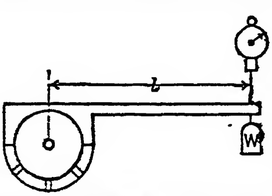

Fig. 6. Stationary Torque Test

LOAD TEST. To make this test on a small machine a prony brake is required: for a large machine a d-c generator may be conveniently employed as a load. The induction motor and generator are direct-connected if possible, otherwise belted together. All the constants of the generator are determined, so that its losses under any condition may be calculated. The motor is then allowed to drive the generator, the rated voltage being impressed upon the motor, and the generator is loaded by means of a rheostat or a water-box so that any load may be obtained. The voltage across each phase of the motor, the current in each phase, the total watts input (by two meters), speed, and, if possible, slip (by a slipmeter, see below) are all read. Care must be taken that correct voltage and frequency are supplied to the motor. The load on the motor is increased step by step to the maximum output point, which is easily known, since when it is reached a decrease in speed is not accompanied by any increase in output of the motor. The motor is still stable at the maximum output condition, since maximum torque occurs at a lower speed than maximum output.

After the load run the d-c generator is run as a motor with the same field strength as before, to determine the mechanical losses, first driving the induction motor at the proper speed, and then running alone at the same speed or speeds at which it ran in the load test. The no-load friction of the induction motor as previously determined in the Excitation Test being known, the increase in friction due to the belt and load is determined and half of it charged against the motor. Let

EI = the output of the d-c generator, in watts.
$I^2 R$ = the hot resistance loss in the d-c armature.
CT = the counter torque or stray power losses in the d-c generator plus one-half belt loss.
P_0 = watts input to induction motor.

Then efficiency of the motor $= \dfrac{EI + I^2 R + CT}{P_0}$.

From these tests, curves may be plotted for the speed, efficiency, power factor, current, and torque of the induction motor for any horsepower output.

Use of Stroboscope to Measure Slip. One type of slipmeter consists of a disk which is attached to the motor shaft and on which alternate sectors of black and white are shown,

preferably as many black sectors as there are poles on the motor. If this rotating disk is illuminated by means of an arc light or neon lamp supplied with the frequency impressed on the primary of the motor, the disk will appear to rotate at a speed proportional to the difference between synchronous speed and actual running speed. The number of these revolutions for 1 minute will be the slip in turns per minute, which may be translated into a fraction or percentage of synchronous speed.

HEAT RUNS. On machines of moderate size heat runs are advisable, but on large machines heat runs are expensive. It is not always necessary to make a heat run in order to know whether the motor is properly designed, as the losses can be accurately calculated from the excitation and short-circuit tests, and the machine may be run without load but with losses equivalent in value to the losses at full load. The usual heat run consists in operating the machine at a certain output for a period from 3 to 6 hours, depending on the size, measuring the resistance before and after the run, and taking temperatures by thermometer on the following parts after the run: primary winding, the iron surfaces in the air gap, secondary winding, bearings, frame.

A heat run which will indicate whether there is anything radically wrong with a motor consists in operating it for an hour or two with a voltage 15 per cent above normal, but without load.

INSULATION TESTS. High-potential tests are made on the primary in the manner described under Testing in the article on Alternating-Current Generators. The value of the high potential for the primary is chosen in accordance with its rated voltage from the Standardization Rules of the A.I.E.E. (q.v.). The potential applied to the secondary, however, has no relation to the rated voltage of the machine; as the working potential in the secondary is low, 1000 to 1500 volts is the usual range of testing potential for the secondary.

18. CALCULATION OF PERFORMANCE

The performance of an induction motor at any load may be determined directly from the load tests described above, or the performance at any load may be calculated from the excitation and short-circuit tests by either of the two methods given below. These methods are also applicable to the calculation of performance from the values of the constants calculated from the dimensions of the machine. The first method is given in detail by Steinmetz in his Elements of Electrical Engineering, and the Heyland Circle Diagram is given by McAllister in his Alternating Current Motors. The former is recommended where accuracy is desired and the latter (graphical) for the student desiring a general understanding of the relations.

STEINMETZ METHOD. This method is based upon the equivalent circuit of a transformer, as given in the article on Transformers. Let

E = impressed voltage per phase.

m = number of phases.

r_1, r_2, x_1, x_2 = resistance and reactance of primary and secondary, respectively, per phase and reduced to terms of primary.

s = slip as a decimal fraction (assumed).

g = primary no-load conductance = $\dfrac{\text{core loss}}{mE^2}$.

b = primary no-load susceptance = $\dfrac{I_m}{E}$.

Assume a slip s and calculate

$$a_1 = \frac{sr_2}{s^2x_2^2 + r_2^2}$$

$$a_2 = \frac{s^2x_2}{s^2x_2^2 + r_2^2}$$

$$g_1 = g + a_1$$

$$b_1 = b + a_2$$

$$c_1 = 1 + r_1g_1 + x_1b_1$$

$$c_2 = g_1x_1 - b_1r_1$$

Then

Counter emf per phase $\qquad e = \dfrac{E}{\sqrt{c_1^2 + c_2^2}}$

Current per phase $\qquad I = e\sqrt{g_1^2 + b_1^2}$

Total volt-ampere input to motor	$P' = mEI$
Watts input to motor	$P = me^2\,(g_1 c_1 - b_1 c_2)$
Watts output of armature	$P_0' = me^2 a_2\,(1 - s)$
Watts output of pulley	$P_0 = P'_0 -$ (friction in watts)
Efficiency	$\epsilon = \dfrac{P_0}{P}$
Power factor	$\cos\varphi = \dfrac{P}{P'}$

CIRCLE DIAGRAM OR GRAPHICAL METHOD. The method of the circle diagram is based on the fact that the electrical reactions in an induction motor (or transformer) may be represented without any great error by the reactions in two parallel inductive circuits as in Fig. 7. I_e and I_m represent the two components of the exciting current, which is assumed constant. R_m and X_m represent the total resistance and reactance (both assumed constant) of the motor and are in series with a variable resistance R_L representing the load.

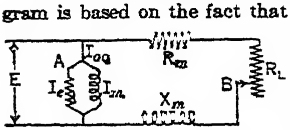

Fig. 7. Equivalent Circuit

The vector relations of the currents are as shown in Fig. 8, where

OE = the impressed voltage per phase
OM = the current I_{00} in A
MP = the variable current in B (not drawn)

Since the current represented by MP is equal to $\dfrac{E}{\sqrt{(R_m + R_L)^2 + X_m^2}}$, as R_L varies the point P will describe a circle through M, P and F, where $MF = \dfrac{E}{\sqrt{R_m^2 + X_m^2}}$. The total or resultant current will then be OP.

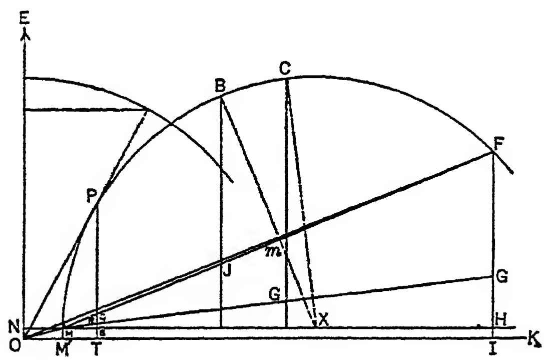

Fig. 8. Circle Diagram

Heyland Circle Diagram. The circle diagram upon which the following discussion is based is a modification of Heyland's transformer, or induction motor diagram.

Let (see Fig. 8):

OE = impressed voltage per phase.
OK be at 90 deg to OE.
OM = exciting current per phase, drawn in phase and magnitude.
OF = short-circuit current per phase, drawn in proper phase and magnitude.
IF = energy component of OF.

Join M and F; then MF is the secondary short-circuit current in terms of primary circuit.
Bisect MF at m.
Draw mX perpendicular to MF at middle point, intersecting NH at X.
With X as center and either XM or XF as radius, draw the semicircle MCF. This is the locus of the primary current.
Since $OE \times IF$ = watts input at standstill, draw HG such that $OE \times HG$ = primary I^2R at standstill.

Then $OE \times GF$ = secondary I^2R at standstill.
Draw GM. The vertical distance between GM and NH at any point gives a current which if multiplied by OE gives the power loss in primary.
Choose any point P on circle; then OP = current per phase.
Then $\cos \sphericalangle POE = \cos\phi$ = power factor.
MP (not drawn) = secondary current reduced to primary turns.

- $PT \times OE$ = power input to primary, in watts.
- $TS \times OE$ = no-load loss, in watts.
- $QT \times OE$ = total motor loss.
- $RT \times OE$ = total primary loss in watts.
- $RS \times OE$ = primary copper loss, in watts.
- $PR \times OE$ = secondary input, in watts.
- $QR \times OE$ = secondary copper loss, in watts.
- $QP \times OE$ = motor output, in watts.
- $OM \div OP$ = per cent magnetizing current.
- $M'T \div OP$ = per cent leakage reactance voltage.

These are all per phase

Draw XC perpendicular to MG and CG' perpendicular to NH.
Then $CG' \times OE$ = maximum torque in synchronous watts.
Draw XB perpendicular to MF and BJ perpendicular to NH.
Then $BJ \times OE$ = maximum output in watts.

- $QR \div RP$ = per cent slip (in case of induction motor).
- $OP \times OE$ = volt-amperes input.

Torque in pounds at 1-ft radius $T_s = (PR \times OE) \times m \times \frac{7.06}{N}$, where m = number of phases and N = synchronous speed in revolutions per minute.

CHARACTERISTIC CURVES. The observed or calculated values (by either of the above methods) of the slip, power factor, efficiency, apparent efficiency, current

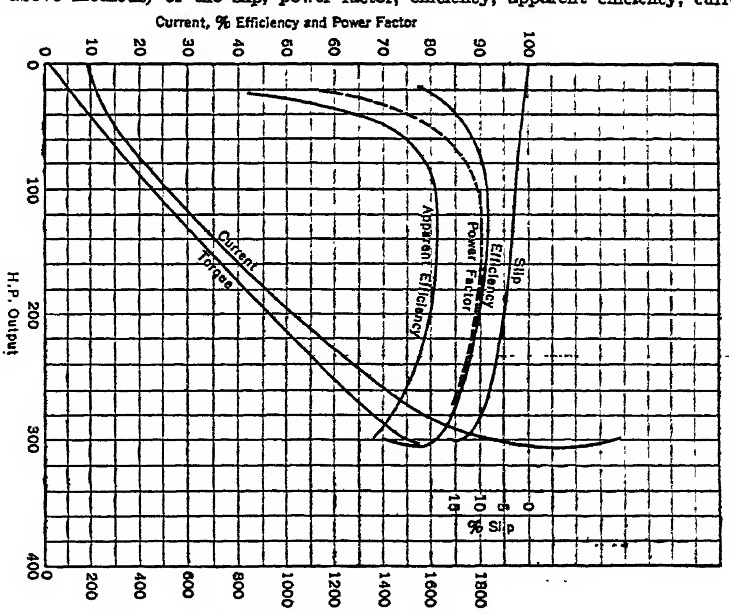

Fig. 9. Characteristic Curves of an Induction Motor

per phase, and torque may be plotted as ordinates with horsepower output at the shaft as abscissas. An example of the characteristic curves thus plotted is shown in Fig. 9. Usual values of the various quantities for different sizes of motors at rated load are given above. The "power factor" shows the relation between the true power input of the machine and the apparent power, called the "volt-amperes." A poor power factor does not involve any greater registration of the watthour meter or cost of energy to

operate the motor, but it does involve poor regulation of voltage in the system as a whole and larger capacity of wiring, transformers, etc. The "apparent efficiency" is equal to the product of the power factor and efficiency, or is equal to the ratio of output in watts divided by input in volt-amperes. Its value determines the actual capacity of the lines and transformers supplying the motor.

EXAMPLES OF DESIGN AND PERFORMANCE. In the accompanying tables are given the essential data for both mechanical and electrical features of six three-phase induction motors. The list of items will be found useful as a guide in collecting data on various machines. Performance data are deduced from tests.

19. METHODS OF STARTING

In order to start an induction motor of any size without injurious heating, either a resistance must be connected in the secondary circuit or the voltage impressed on the primary must be reduced. The two general methods of starting induction motors are known as "potential control" and "rheostatic control." The same methods are used for speed control (see below).

STARTING BY "POTENTIAL CONTROL" METHOD. This method consists of reducing and regulating the voltage impressed on the primary, usually by means of a starting compensator or auto-transformer which provides one or two fractional voltages. In order to make use of this method the secondary must be of higher resistance than with other methods of starting. For this reason, and because there is no need of making any change in the windings, a squirrel-cage rotor winding is customarily used with this method of starting. This winding is made up of one bar per slot, and all bars are connected at both ends to rings. To start the motor the primary is connected to taps on the compensator which give a voltage of $1/2$ to $2/3$ the rated voltage if it is a small motor, and $1/3$ to $1/2$ if it is a large motor. A small motor may be brought up to full speed on this voltage, but a large motor may require an intermediate step. The connections are shown in Fig. 10. It is customary to adjust the motor resistance and starting voltages to give the relations in Table 10.

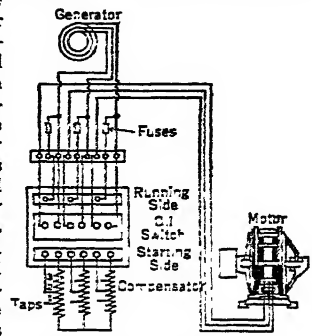

Fig. 10. Potential Control

BOUCHEROT WINDING. This type of winding for the rotors of induction motors is a device designed to give good torque at starting by means of high secondary resistance and inherently to reduce this resistance as the motor accelerates, so that at full speed the secondary resistance will be low, the slip small, and the efficiency high.

The device consists of two independent windings on the secondary (usually squirrel cage): one, a high-resistance winding of brass or German silver bars is placed near the periphery of the rotor in the usual form of slots; the other winding, of low resistance (large copper bars), is placed in slots like tunnels below the bottom of the surface slots. A narrow slit or shaft extends from the bottom of the outer slot to the top of the inner slot.

Table 10. Starting Conditions

Voltage on Motor, per cent	Current in Line, per cent	Starting Torque, per cent
33	75	22
50	175	50
66	300	88
100	700	200

The outer winding acts like any high-resistance winding, giving good starting conditions. The inner winding is so highly inductive that at standstill, when the secondary has full frequency, it has a very high reactance, carries very little current, and contributes but little to the action of the motor. At speeds near synchronism the secondary frequency is very low (of the order of one cycle per second), the reactance is low, and the inner low-resistance winding carries most of the current; consequently under running conditions the motor has practically the same characteristics as one having a single low-resistance secondary.

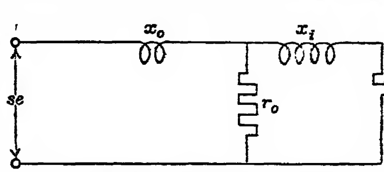

Fig. 11. Boucherot Double Squirrel-cage Winding

Boucherot Double Squirrel-cage Winding.

r_i = resistance of inner winding, low.
x_i = reactance between two windings, high.
r_0 = resistance of outer winding, high.
x_0 = reactance between outer winding and primary.

$$Z_i = r_i + jx_i$$

$$Y_i = \frac{r_i - jx_i}{Z_i^2}$$

$$Y_i + Y_0 = Y_i + \frac{1}{r_0} = \frac{r_i r_0 - jx_i r_0 + Z_i^2}{r_0 Z_i^2}$$

$$Z_{i0} = \frac{r_0 Z_i^2}{r_i r_0 - jx_i r_0 + Z_i^2}$$

$$Z_2 = Z_{i0} + jx_0 = \frac{r_0 Z_i^2 + jx_0 r_i r_0 + x_i r_0 x_0 + jx_0 Z_i^2}{r_i r_0 - jx_i r_0 + Z_i^2} = r_2 + jx_2$$

≡ the equivalent resistance and reactance of the combined windings for substitution in all calculations of characteristics.

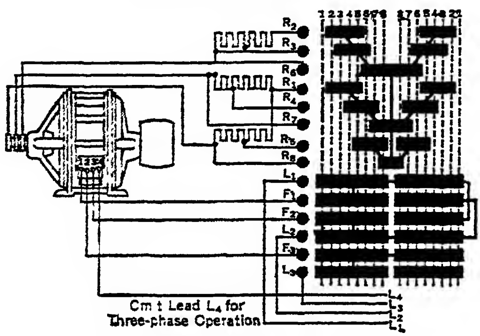

Fig. 12. Rheostatic Control

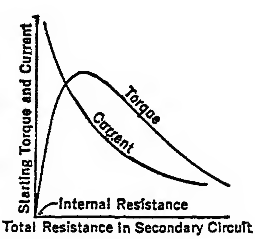

Fig. 13. Starting Resistance, Torque, and Current

STARTING BY "RHEOSTATIC CONTROL" METHOD. Better apparent torque efficiency, that is to say, more torque for a given current, is obtained by inserting in the secondary circuit a much greater resistance than can be left permanently in circuit. This is accomplished by having a special starting resistance connected in series with the armature winding and a switch for short-circuiting the resistance either step by step or as a whole, as the motor speeds up (see Fig. 12). There are two practical methods of doing this:

The first is intended to be used only when the torque required at starting is not very great, in which case the starting resistance may be small and located inside the armature spider. The switch lever is so arranged that the resistance can be short-circuited in steps while the armature is revolving. This obviates the need of collector rings and external connections.

The second method consists in bringing the three terminals of the secondary winding to collector rings. From brushes bearing on these rings conductors lead to external resistances with steps or taps so that the resistance may be short-circuited gradually. This scheme is used where a large starting torque (greater than full-load torque) is required. It may be used also for speed control as shown in Fig. 12.

The proper value of resistance per phase in the secondary is determined by the relation

$$\text{Torque in pounds at 1 ft} = \frac{E^2 r_x}{Z^2} \times \frac{7.06\, m}{\text{rpm}} = \frac{7.06\, m r_x E^2}{N Z^2}$$

where E = primary voltage per phase.
r_x = total secondary resistance per phase in terms of primary.
$Z = \sqrt{(r_1 + r_x)^2 + X^2}$, where r_1 is the resistance per phase of primary and X the total reactance per phase of both primary and secondary.
m = number of phases.
N = synchronous speed in revolutions per minute.

The relation between starting torque and total resistance of the secondary is shown by the curve in Fig. 13.

20. SPEED CONTROL OF INDUCTION MOTORS

The speed of an induction motor may be controlled in five ways:

(a) By varying the potential applied to the primary of motor having a suitable permanent resistance in the secondary.
(b) By varying the resistance in the secondary circuit.
(c) By changing the connections of the primary winding in a manner to change the number of poles.
(d) By varying the frequency of the applied voltage.
(e) By connecting the secondary of one motor to the primary of another, called the "concatenation" method of control.

POTENTIAL CONTROL OF SPEED. This method is an elaboration of the potential-control method of starting. A suitable resistance or auto-transformer reduces the impressed voltage to the fractional value desired (two-thirds is the usual ratio). The auto-transformer wastes less power than a resistance but is more expensive. Because of the reduced voltage, the flux and torque-per-ampere are reduced and more current will be required for a given torque. The induction motor should have a very large resistance in the secondary, which is preferably of the squirrel-cage type. This resistance gives the motor a speed characteristic such that its full-load speed is some 10 per cent less than that of a normal motor. As the load is increased the speed may fall to about 30 per cent of the no-load value without the motor breaking down or falling out of step, which in the normal motor usually takes place at about 80 per cent of the full-load speed. This motor is not stable in speed as each slight change in the load will cause a change in the speed more or less inversely proportional to the load. The advantages of this method of control are the simplicity of the connections and devices. The disadvantages are the greatly increased heating in the motor itself with the decreased speed. Thus the motor must be larger than if other speed-control methods are used. Table 11 shows the efficiencies obtained.

RHEOSTATIC CONTROL OF SPEED. With this method (an elaboration of the method of the same name for starting) the secondary or rotor must have a definite winding (which costs more than the squirrel-cage winding used in the preceding method) with slip rings and brushes to lead out the current. The friction and resistance losses due to these brushes decrease the efficiency of the motor a slight amount. The action of this method is based on the principle that in an induction motor the drop in speed for any given torque is proportional to the resistance of the secondary circuit.

Assuming a motor which has at full speed a net resistance of the secondary proper of 1 ohm, the speed-torque curve would be as shown for $R = 1$ in Fig. 14. This motor would have a slip of 5 per cent for full-load torque and of 25 per cent for maximum torque, a torque at starting of 80 per cent of full-load torque and a very large starting current. If by some means this resistance is doubled the speed-torque curve would be as shown for $R = 2$, which shows a slip of 10 per cent for full-load torque and of 50 per cent for maximum torque. For $R = 5$, $R = 8$, etc., there would be other speed curves. By starting with a resistance of 8 ohms a torque of about 200 per cent of full-load torque would be obtained at starting with about twice full-load current. By allowing the motor to follow this curve until the torque has dropped to the full-load value, the motor would reach 60 per cent of synchronous speed, or 40 per cent slip. Then by reducing the resistance in steps the torque and speed would follow the heavy zigzag line until the motor reached full speed.

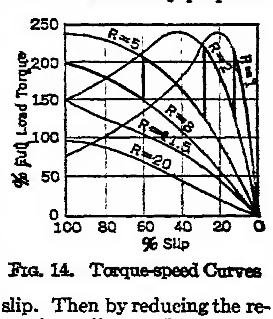

Fig. 14. Torque-speed Curves

With this method of control the torque per ampere remains practically constant as in a shunt motor regulated by resistance in the armature circuit. The efficiency varies directly with the speed as shown in Table 11.

The advantages of this method are the higher efficiency and particularly the smaller losses in the motor itself. The losses are in the rheostat. The disadvantages are the necessity of collector rings, brushes, controllers, etc. The motor is not stable at any fractional speed but the speed will change with every change of load.

CHANGE OF POLES TO CONTROL SPEED. By a proper design of the windings an induction motor may be made to operate with either 4 or 8 poles, 6 or 12 poles, or even 4 or 6 poles or 6 or 8 poles. This is accomplished by a throw-over switch to which

taps from the windings are brought. In this arrangement the pitch of the primary winding must be made a compromise between the proper value for the different numbers of poles, and therefore the constants of the motor are not as good as those of a standard motor. It is also necessary to use a squirrel-cage armature, since this is suitable for any number of poles without change of connection. This type of motor operates advantageously only at the two speeds corresponding to the two arrangements of poles and is stable at each of these speeds. If a wider range is desired the potential-control scheme may be combined with it. The speeds and efficiencies with this scheme of control are given in the following table. At half-speed the efficiency is almost double that obtained with the other methods, but the losses in the motor are greater than with the rheostatic control.

Table 11. Comparison of Methods of Speed Control

(For constant torque equal to torque at full load)

Nominal Speed	Potential			Rheostatic			Change of Poles		
	Speed	Volts	Eff.	Speed	Volts	Eff.	Speed	Volts	Eff.
No load	1.00	100	....	1.00	100	....	1.00	100	....
Full speed	0.89	100	81	0.96	100	86	0.96	100	86
Three-quarter speed	0.67	66	59	0.72	100	65	....	....	....
Half speed	0.45	57	37	0.48	100	43	0.48	100	74
Quarter speed	0.22	56	17	0.24	100	22	....	....	....

CHANGE OF FREQUENCY METHOD OF CONTROL. The speed of an induction motor at any load varies directly with the frequency of the supply circuit. If two circuits from two alternators of different frequencies are provided the motors may be connected to one circuit for one speed and to the other circuit for another speed. This method of speed control requires as many separate generators and circuits as the number of speeds desired. It is, therefore, costly and not widely used.

CONCATENATION CONTROL OR CASCADE CONTROL. If two motors have definite windings in both the primary and secondary and are rigidly connected to a common shaft, they may be operated at a fractional speed corresponding to a number of poles equal to the sum of the number of poles on the two motors. With the concatenation control the primary (stator) of motor 1 is connected to the supply circuit, the secondary (rotor) of 1 is connected to the primary (rotor) of 2, and the secondary (stator) of 2 is connected to a resistance which is eventually short-circuited. When the two motors have the same number of poles, which is the usual commercial condition, motor 1 transforms half the power into mechanical power at the shaft at *half speed* and the remainder into electrical power at half frequency. Motor 2 receives this electrical power and transforms it into mechanical power at this same speed. If the number of poles is different, the speed in rpm of the combination is

$$N = \frac{120 f}{p_1 + p_2}$$

These simple relations are exact only on the assumption of no losses and the secondary of 2 short-circuited.

The objections to this method of control are that the first motor has to carry the magnetizing current of both motors, thus having a low power factor. The first motor must receive the power for both motors; therefore, it must be the larger of the two and specially designed or there is an inefficient use of material in the second motor. If the two motors are alike (the usual commercial condition) the torque of the two motors in concatenation is not as great as that of the two motors in parallel.

The efficiency at fractional speed is, however, better than with the rheostatic method of control. Only two "free-running" speeds are available with two motors having the same number of poles. This scheme has been adopted frequently for the speed regulation of induction motors used on electric locomotives in foreign countries. In such applications it is frequently the custom to allow one motor to be idle at the higher speed.

21. INSTALLATION AND OPERATION

Induction motors are usually built, even in large sizes, as a unit including the bearings, which are usually a part of the end frame of the motor proper. They may be either direct-connected or belted to their load, but the latter method is more general, since each induction motor can be built for only a certain definite speed corresponding to a certain number of poles. The smaller motors need no foundation, and in fact are fre-

quently attached to the wall or to the ceiling, the bearings and end shield being made in such manner that they may be turned through 90 deg or 180 deg so that the oil rings will operate properly under these conditions. In most motors, reasonable ventilation, free from dust and dirt, must be available. For certain applications, such as cement mills or mines, the motors are built totally enclosed and may then be even submerged in water. In this case, of course, a motor of a given rating is larger and more expensive than one of the open type.

Small motors are designed to start merely by closing the main switch. With larger motors, if the starting switch is at the proper position, potential may be applied to the motor and the starting resistance gradually cut out by moving the switch.

Induction motors are very sensitive to variation in the impressed voltage. A decrease in impressed voltage from 100 to 80 would cause the maximum output and maximum starting torque to decrease from 100 to 64 and roughly would cause a proportional increase in the heating for a given load.

Unequal voltages in the different phases also cause a decrease in the maximum output and an increase in the heating for any given output. An unbalancing of 25 per cent in voltage would double the heating effect at full load, i.e., would give the same heating as an overload of 50 per cent.

CARE IN STARTING. Before starting the motor for the first time it is desirable to make sure that the starting device is in operating condition and in the proper position, in order that the motor should not become injuriously heated. Attention should be paid to having the wiring so proportioned as to carry the starting current without an excessive drop in voltage (see above).

FAULTS. Some of the more common faults occurring in induction motors, together with their signs and remedies, are the following.

Secondary Open-circuited. The motor will not start and will not take a current greater than the exciting current. The cause is probably due to the starting resistance not being connected in.

One Phase of Secondary Open-circuited. The motor has a tendency to remain at half synchronous speed although the current is apparently normal. If the armature is blocked it will be found that the current in the three phases will be unbalanced.

One Phase of Primary Open. The motor will not start and the current will be unbalanced.

One Phase of Primary Reversed. The currents in the primary will be very much unbalanced when the motor is running and the starting torque will be very slight.

Short-circuited Coil in Primary. There will be humming when potential is applied to the motor and excessive local heating around the short-circuited coil.

Vibration. Vibration due to mechanical unbalancing is chiefly noticeable at high speeds and particularly in high-speed machines. If the vibration is due to magnetic unbalancing it is probably caused by inequality in the air gap at different portions of the circumference and with different positions of the armature. This may be detected by measuring the air gap with taper wedges at various points around the circumference, first with the armature in one position then in several other positions.

SPECIFICATIONS FOR INDUCTION MOTORS. The following memoranda are intended to assist in writing specifications. See also article on Specifications.

Principal Characteristics and Conditions of Service. Use to which motor is to be put; kind of load and method of drive. Voltage and number of phases. Rating, horsepower. Frequency and speed.

Style and Description; Details of Construction. Whether to be open, semi-enclosed, or enclosed. Requirements regarding pulley or length of shaft. Whether rails are required. Method of starting; compensator, external resistance or internal resistance; whether motor is to be run at speeds other than full speed. Whether the starting devices are to be supplied.

Performance and Tests. (See Standardization Rules of the A.I.E.E.). Temperature rises upon which ratings are to be based. Details of overload capacity. Efficiency at 25, 50, 75, 100, and 125 per cent load. Starting torque with full-load current, pound-feet. High-potential tests of insulation. Requirements regarding effect of moisture upon insulation.

SINGLE-PHASE INDUCTION MOTORS

A two- or three-phase induction motor may be operated as a single-phase machine after it is brought up to speed. Under these conditions it operates at a lower efficiency, at lower power factor, and with a lower maximum output than it would have as a polyphase motor. The slip for a given output is less in a single-phase than in a polyphase motor.

LOAD AND VOLTAGE RATING. On account of the poorer operating characteristics and particularly on account of the lower maximum output or maximum torque, it is necessary to rate the motor at a lower capacity. When a three-phase motor is operated single-phase with the same voltage between lines, its maximum output will be approximately 40 per cent of the three-phase maximum output.

For best conditions, such as best distribution of losses and ratio of rated to maximum output, it is customary to use a three-phase motor, to reduce the rated output of the motor, and to increase the rated terminal voltage in a definite ratio. Thus, if P be the rated output, in watts, of a given motor when operating on a three-phase circuit having a voltage between lines equal to E, then it would be advisable to operate the motor single-phase with a voltage between lines equal to 1.3 E, and to assign the motor a rating of 0.67 P to 0.75 P.

This will result in a distribution of losses in the motor quite similar to that which obtains during three-phase operation. The maximum output as a single-phase motor (at the higher voltage) will be about 67 per cent of the maximum output of the three-phase motor. The efficiency and power factor will be reasonable.

If the voltage of the single-phase supply circuit must be the same, the winding of the motor is changed to give about 75 per cent as many turns in series per phase as for normal three-phase operation.

EXCITING CURRENT AND POWER FACTOR. At a given voltage between terminals the volt-amperes input at no load for excitation are practically the same for single-phase and polyphase operation. Thus the no-load current of a single-phase motor is considerably greater than when operating polyphase. The increase in the applied voltage or the decrease in the number of turns makes a still greater increase in the magnetizing current. Thus the power factor of a single-phase motor is very poor at light loads and not very good at rated load.

22. CALCULATION OF PERFORMANCE

To predetermine the characteristics of a single-phase motor it is calculated as a three-phase motor for the same voltage between lines as the single-phase circuit. The magnetizing current, core loss, resistance per phase, and reactance per phase are all calculated as usual. The motor primary may be connected either delta or Y, but for purposes of calculation it is desirable to pro-rate the constants of a Y-connected motor on the assumption that it is delta connected.

To pro-rate the resistance and reactance per phase of primary and secondary, multiply the values for a Y-connection by 3 to obtain the values for the equivalent delta constants. The voltage per phase is presumed to increase in the ratio 1 to 1.73, while the voltage between lines remains the same.

The single-phase magnetizing current is found by dividing the volt-amperes excitation for three-phase conditions by the single-phase voltage. The core loss in watts remains practically the same single-phase, and the energy component of the single-phase exciting current is equal to core-loss watts divided by rated voltage.

The resistance and reactance of the primary of a single-phase motor are taken the same as the equivalent delta values per phase.

The resistance and reactance of the secondary of a single-phase motor are taken as $1/_3$ of the three-phase equivalent delta values.

These values are then substituted in the formulas of the Steinmetz method (see Motors, Polyphase Induction) and the characteristics calculated for several assumed values of slip. The only difference in calculation is that the torque in synchronous watts is

$$T = e^2 a_1 (1 - s)$$

and the output of the armature is

$$P = e^2 a_1 (1 - s)^2$$

It is of course understood that in a single-phase motor the output calculated for one phase is also the total output of the motor.

23. METHODS OF STARTING

A single-phase motor has no torque at standstill. It must be started by some device such as a phase-splitting device. It may be started in either direction, and as soon as it starts to rotate a slight torque develops which increases with the speed. When this torque has reached a great enough value to overcome the friction and inertia the special starting apparatus may be disconnected and the motor will continue to accelerate to its proper speed.

STARTING OF SMALL MOTORS. Small motors may be started without auxiliary electric circuits by giving the armature a spin by hand, after which (if there is no load) they will accelerate. Certain small motors are designed with a loose pulley which is clutched at a predetermined speed of the armature by means of a centrifugal governor. These motors are provided with "shading coils" or a small external phase-splitting device, to give them just enough starting torque to overcome their own friction.

STARTING OF LARGE MOTORS. A phase-splitting device is generally used; either a reactor and resistor or a condenser and resistor may be employed. Commutator devices are also used.

Use of Reactance Coil and Resistor. The connections employed are shown in Fig. 1. This device consists of a resistance and a reactance connected so as to advance the phase of the emf impressed on one circuit of the motor and retard the phase of the emf on another circuit, while the line voltage is impressed on the third winding. This may be accomplished either by connecting the resistance and reactance across the line terminals and in multiple with the motor windings as shown in Fig. 1A, or by connecting the resistance and reactance in series with the respective windings as shown in Fig. 1B.

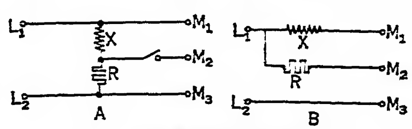

FIG. 1. Phase Splitting Circuits

In these figures L_1 and L_2 represent line terminals, R is the resistance coil, X the reactance coil, and M_1, M_2 and M_3 the three motor terminals. The former method gives a greater starting torque but takes a greater current in proportion to the torque. The latter method is more efficient. The motor must have sufficient resistance in its secondary circuit to give good starting characteristics as a three-phase motor.

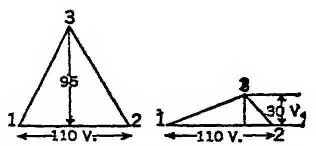

FIG. 2. Split Phase Vector Diagram

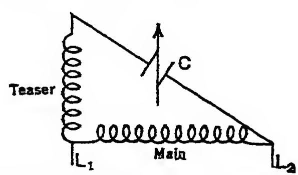

FIG. 3. Principle of Connection of a Capacitor Motor

The principle of this device is that the voltages between the outside terminals and the middle point are out of phase with each other and form a somewhat flattened vector triangle similar to that of an unbalanced three-phase system. The ratio of the starting torque obtained with such a device to the normal starting torque with balanced three-phase voltages is the same as the ratio of the altitude of the triangle of vector voltages to the altitude of the equilateral triangle. Thus in Fig. 2 the ratio of altitudes is 30/95 = 0.316; thus the single-phase starting torque would be 31.6 per cent of the three-phase starting torque.

Capacitor Motor. If a condenser of the proper capacitance (see Fig. 3) is substituted for the resistance the starting torque will be increased and the efficiency and power factor

improved, but this is much more expensive and frequently involves the use of an auto-transformer across the condenser to put a higher voltage across the condenser and reduce the required capacitance. Many small fractional horsepower single-phase motors use this principle by connecting a condenser (and auto-transformer) in series with a quadrature winding in the motor and connecting this combination in parallel with the main winding. Usually a centrifugal switch is used to cause the auto-transformer to put a high voltage across the condenser in starting and a lower voltage while running, thus giving a high starting torque by momentarily overloading the condenser, and normal conditions for running. Such motors have a good power factor and cause little radio interference because there is no commutator. They are used for refrigerators, oil burners, etc.

Use of Commutator. Another method of starting single-phase motors involves the use of a commutator which permits the motor to start as a repulsion motor (which has good starting qualities; see A-c Commutator Motors), and after the motor has reached a considerable speed the brushes are removed from the commutator and a short-circuited squirrel-cage winding comes into play.

ALTERNATING-CURRENT COMMUTATOR MOTORS

There are several different types of alternating-current commutator motors designed to operate on single-phase circuits, but they differ chiefly in the electrical connections employed. They may be divided into two general classes, series motors and repulsion motors. While these motors differ in their connections and in slight details in their

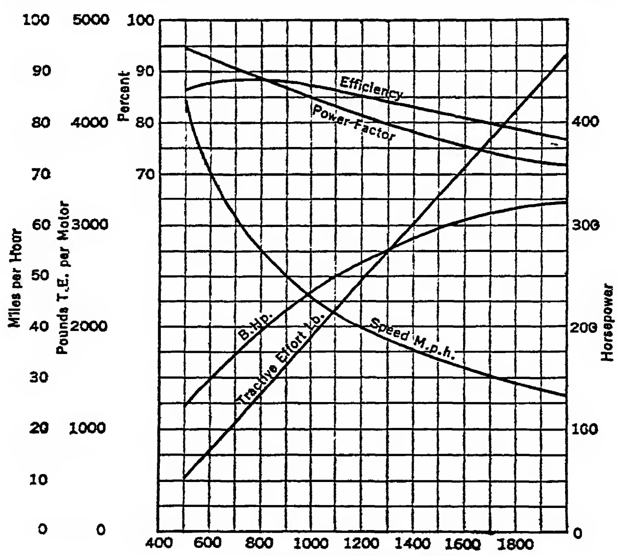

FIG. 1. Characteristic Curves of Series Compensated Single-phase Motor for 25 Cycles

characteristics, they all have the general characteristics of the d-c series motor, that is, increasing torque with decreasing speed and a high efficiency over a considerable range of speed. Alternating-current commutator motors with shunt motor characteristics are also used to a limited extent abroad.

GENERAL CHARACTERISTICS. The torque of any single-phase a-c commutator motor is constant in direction, but pulsating in value, and its average value is proportional to the product of the effective value of the flux and the effective value of the armature current. The direction of the torque may be changed by changing the direction of the current in the field with respect to the armature, or vice versa. The power factor increases with increase of the speed and therefore decreases with increase of load. The efficiency, though not as good as that of a d-c motor of the same rating is, however, fairly high. The motors have in addition to the losses common to d-c motors a core loss in the field, increased core loss in the armature, increased commutation loss, and increased RI^2 loss in special windings. In Fig. 1 are given the characteristic curves of the a-c compensated series motors used on the single-phase locomotives of the New York, New Haven & Hartford Railroad.

APPLICATIONS. The most general application of a-c commutator motors in large sizes is in railway and hoisting work; see Sections 16 and 17. The same principles of operation are made use of in the devices for starting single-phase induction motors (see Art. 23), the motor being brought up to speed as an a-c commutator motor and then by a change of connections made to operate as a single-phase induction motor.

24. DESIGN

The salient features in the design of the various types of a-c commutator motors are described briefly below.

STRAIGHT A-C SERIES MOTOR. Since the torque of an ordinary d-c series motor does not change in direction when the current through both the field and the armature reverses simultaneously, any d-c series motor will develop a unidirectional torque when connected across a-c mains. However, when an ordinary d-c series motor is thus used the power factor of the load taken by it is very low, there is a large eddy-current loss in the field structure, and violent sparking occurs at the commutator. To make a series motor practicable for a-c service, the field structure must be laminated in order to avoid eddy currents and the field coils must have only a few turns to avoid too great self-inductance, and the consequent low power factor. The greater tendency to spark in the case of the a-c series motor is due to the *alternating* field flux which interlinks the coils short-circuited by the brushes, thus inducing in these coils a relatively large emf not present when the motor is operating on a d-c circuit. This difficulty can be avoided to a certain extent by designing the motor for a small field flux and with but a few turns in series in each armature coil. In general, therefore, single-phase commutator motors are built for low voltages, such as 200, with one turn per coil, multiple-wound armatures, and with the armature ampere-turns per pole about four times the field ampere-turns per pole. The effect of the armature ampere-turns can be neutralized by a "compensating" winding described below. The field flux is practically limited to that value which will give 4 volts per turn in the short-circuited armature coil, as this is about the limit that may be commutated with carbon brushes.

Resistance Leads. As an additional means of preventing sparking, high-resistance leads are frequently used between the commutator segments and the armature coils. These leads are made of a high-resistance metal strip bent back and forth several times, and imbedded in the armature slots along with the armature conductors proper. On account of the dissipation of heat in these leads a lower current density must be used in the armature conductors proper than is used in the case of d-c motors. The arrangement of the leads is such that the main or useful current passes through two high-resistance leads in multiple as it enters the armature, while the undesirable short-circuited current passes through two high-resistance leads in series. It should be noted, however, that at any instant there is current only in those leads connected to coils which are being short-circuited at this instant.

Compensating Winding. To obviate the high armature reaction in an a-c series motor and at the same time to improve the power factor, a "compensating" winding is usually employed. This consists of a distributed winding imbedded in slots in the pole faces and connected usually in series (Fig. 2) with the main field winding and armature in such a manner that the current through it sets up a magnetomotive force which practically neutralizes the effect of the armature ampere-turns. When the compensating winding is connected in series with the field and armature, as shown in Fig. 2, the motor

is said to be "conductively compensated." An "inductively compensated" motor has this winding short-circuited upon itself and the current in it is induced from the armature by transformer action. Inductive compensation is not operative on d-c circuits, but is as satisfactory as conductive compensation for a-c operation.

THOMSON REPULSION MOTOR. This motor has a stationary structure or field with a completely distributed winding, which may be wound for any voltage. In this is placed a low-voltage armature designed with all the refinements necessary for single-phase commutator work. The brushes bearing on this commutator are short-circuited upon themselves and are so placed that the line connecting the positive and negative brushes makes an angle α with the neutral axis of the field. The field turns lying within the angle $(90 - \alpha)$ induce a current in the armature winding by transformer action, and the field turns lying within the angle α constitute the "exciting" turns and set up the necessary flux to produce the driving force. The arrangement is equivalent to the circuits shown in Fig. 3, although actually there is but a single field winding. This motor then acts exactly like the combination of a transformer and a series motor in one structure. It may be reversed by changing the position of the brushes or by shifting the points of connection of the external circuit to the field or stator winding. This motor operates particularly well near synchronous speed as then it has practically a rotating magnetic field and no excessive commutation difficulties, but at starting and at low speeds the commutation is not as good as that of the compensated series type.

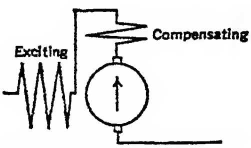

Fig. 2. Compensated Series Motor

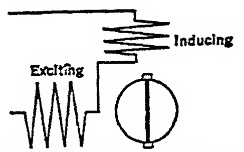

Fig. 3. Thomson Repulsion Motor

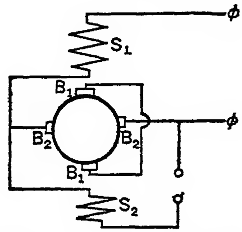

Fig. 4. Repulsion-starting; Induction-running Motor

WAGNER REPULSION-STARTING, INDUCTION-RUNNING MOTOR (Fig. 4). The stator has two windings, the main or primary S_1 is connected in series with the exciting brushes B_2 on the armature as in the series motor. This gives the starting characteristics of the series a-c motor. The armature has two sets of brushes. The main pair B_1 in line with the primary flux is short-circuited, thus giving compensation as in the compensated series motor. The other pair of brushes B_2 is connected in series with the primary and across a "power factor compensating coil" S_2, wound on the stator in the same axis as the primary. A switch in this circuit is left open when starting, but is closed by a centrifugal governor just before synchronous speed is reached. Closing this switch short-circuits this pair of brushes through the compensating coil and makes the armature a two-phase rotor, and thus eliminates series-motor action and makes the action that of a true single-phase induction motor. The compensating coil being in circuit causes the anti-inductive effect in this coil to react on the primary as in the compensated repulsion motor, and give a good power-factor or leading current. By adjusting the number of turns or current in this coil S_2 the power factor may be regulated.

To prevent the motor from running away in case the centrifugal switch should fail to act, and to relieve the brushes under load, a regular squirrel-cage winding is placed in the bottom of the armature slots underneath the commutated winding and separated from it by magnetic separators to magnify the magnetic leakage and render the squirrel-cage winding ineffective at starting. This motor is very satisfactory in practice, has a starting torque 1.5 times full-load torque for a starting current of 3 times full-load current. The power factor is anti-inductive at light loads, unity at full load, and inductive at over-loads. The efficiency at full load is about 80 per cent in the 5- and 10-hp sizes. Reversal of rotation is effected by changing the connections to the exciting brushes. Small motors may be thrown directly on the line for starting. Large motors have a series resistance or reactance to limit the starting current to a reasonable amount.

REPULSION-INDUCTION (R. I.) MOTOR OF THE GENERAL ELECTRIC CO. This motor is shown diagrammatically in Fig. 5. It has two windings on the stator, the main or primary S_1 being connected directly and solely across the line as in any induction motor. The armature has two equally spaced sets of brushes displaced a

small angle (20 deg) from the axis of the primary flux, thus obtaining the repulsion motor starting effect. The main brushes B_1 are short-circuited and the auxiliary brushes B_2 connected permanently in series with the "power factor compensating coil" S_2 on the stator. The method of operation is best understood by considering the motor as being a repulsion motor and a single-phase induction motor on the same shaft. At starting the repulsion-motor torque is great and the induction-motor torque is zero. Just below synchronism the induction-motor torque is great and repulsion-motor torque small. Above synchronism the repulsion-motor torque still exists but the induction-motor torque has become negative (generator). Thus at no load the repulsion motor pulls the induction motor above synchronism until the positive torque equals the negative torque and friction. At full load the speed is nearly synchronous. The compensating coil introduces an anti-inductive effect described above, and by varying the number of turns included, the power factor may be made unity at any load. The efficiency is about 80 per cent in a 5-hp motor. Reversal of rotation is effected by moving the brushes or, if to be done often, by introducing a special coil in the primary whose connection is changed for reversal. An ordinary starting box is used to limit the current to about three times full-load current for 1.5 times full-load torque.

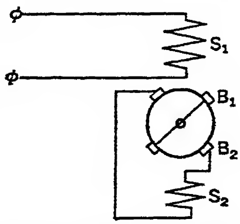

FIG. 5. Repulsion-induction (R.I.) Motor

THE "SCR" MOTOR. The "SCR" motor of the General Electric Co. is a single-phase repulsion-induction motor in that it starts as a repulsion motor and runs at almost constant speed as an induction motor. It is available for operation on 60 cycles, has a starting torque of 200 to 300 per cent of rated, and a starting current of 175 to 200 per cent of rated. It has a good efficiency (80 per cent) and high power factor (93 per cent).

There are two brush studs per pair of poles, but there is no centrifugal switch or change of connection between starting and running, the transition being accomplished by the change in reactance of the squirrel-cage winding. The stator, primary, is wound as a repulsion motor, the winding having two components with respect to the brushes, an exciting and an inducing winding, but both in series with the supply. The rotor carries a d-c multiple drum winding near the surface, and this is connected to a commutator in the usual manner. The slots are of the "Boucherot" type (see Induction Motors) with a deep slot below the outer slots. In these lower slots is a squirrel-cage winding. The leakage of flux between the two windings is carefully proportioned so that at starting and low speeds (high slip frequency) the leakage reactance of the squirrel cage is so great that it is practically inactive, and at high speeds (low slip frequency) the squirrel cage carries most of the load as an induction motor and limits the speed. At no load the repulsion action carries the speed above synchronism, but the motor is stable at this speed and drops about 6 per cent at full load.

THE "BTA" OR SCHRAGE MOTOR. The "BTA" or Schrage motor of the General Electric Co. is a polyphase adjustable-speed motor with a speed range of about 3:1 in which the speed is changed by shifting the relative position of two sets of brushes on the commutator. It gives a starting torque of 140 to 250 per cent of rated with a starting current of 125 to 175 per cent with the brushes in the position for lowest speed. At the high-speed setting its efficiency is 65 to 70 per cent and power factor 90 to 100 per cent; at the lowest-speed setting the efficiency is about 30 per cent and power factor 65 to 70 per cent.

The rotor has two windings: one, the primary, is a usual polyphase winding connected by slip rings to the supply; the other, the "adjusting" winding, is placed in the same slots as the primary and is an ordinary d-c winding connected to the commutator. The stator carries the secondary which is an ordinary three-phase winding with both ends of each phase brought out and each end connected to a separate individual brush stud. Thus there are six brush studs per pair of poles, arranged alternately on two brush yokes, the three beginnings of windings to one yoke and the three ends to the other yoke. The yokes may be moved with respect to each other, which varies the number of commutator segments included in the circuit of each phase of the secondary. The voltage generated by motion of the adjusting winding is of slip frequency and is of zero frequency at synchronism because then the flux of the primary is at standstill in space. The frequency of the voltage of the adjusting winding is the same as that of the induced voltage in the secondary, and the two may be added or subtracted.

With the two brushes of one phase winding on the same commutato segment that winding is short-circuited and the motor acts as an ordinary induction motor and runs just below synchronous speed. With the brushes moved apart one way a voltage is

added to that induced in the secondary by slip, the secondary current is increased, and the motor runs faster. Conversely, if the brushes are moved apart in the other direction a voltage is subtracted from the secondary induced voltage and the motor runs slower. By moving both yokes together the phase of the adjusting voltage is changed, and this must be done in the first place to get the two voltages in proper phase for the best power factor. The direction of rotation is changed by interchanging two of the power supply leads. The motor is started with full voltage. This type of motor is used for blowers, pumps, and compressors.

THE FYNN-WEICHSEL MOTOR. The Fynn-Weichsel Polyphase Induction-Synchronous Motor of the Wagner Co. starts as an induction motor but when once brought up to speed runs as a self-excited synchronous motor whose principal features are its good power factor and its ability to correct power factor. The rotor carries two windings, the true polyphase primary connected to the supply by slip rings and a d-c winding connected to a commutator on which bear two brushes per pair of poles. The stator carries the secondary, which is a two-phase winding with the terminals brought out for connection to a starting resistance as in all induction motors with phase-wound secondaries. But the stator winding consists of two parts in quadrature, and on one of them is impressed the voltage from the brushes on the commutator. As in

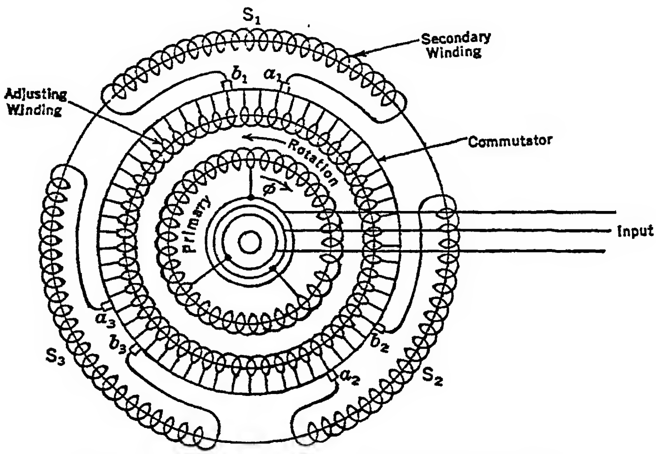

FIG. 6. Bipolar Schrage or B.T.A. Motor (for Two Poles)

the BTA motor this voltage is of slip frequency, hence of zero frequency at synchronism. This voltage is impressed upon one of the stator windings and gives a definite self-excited constant field at synchronism as in the shunt d-c motor. Thus we have a synchronous motor whose primary is revolving and whose field is excited by direct current and is stationary. At synchronism the other part of the stator winding is inactive. The efficiency in a 15-hp motor ranges from 80 to 90 per cent and the power factor may be made anti-inductive. The starting torque and current are like that of any polyphase induction motor started with resistance in the secondary.

TRANSFORMERS

By Walter L. Slichter

The electrical transformer, commonly called the static transformer, is a piece of stationary apparatus used to transform a-c energy at one voltage to some other higher or lower voltage. The single-phase transformer consists of two electrical circuits, usually of a large number of turns, interlinked with a common magnetic circuit of iron. Since the power is approximately the same in both windings, the currents in the two windings are inversely proportional to the voltages in the windings. The polyphase transformer is essentially two or more single-phase transformers made into a single piece of apparatus, but so designed that at least a part of the magnetic circuit is common to all the phases. A three-phase transformer has three high-tension and three low-tension windings arranged on a single iron core; see Figs. 1 and 2.

TERMINOLOGY. The winding by which the energy enters the transformer is logically the "primary," and the one by which the energy leaves the transformer is called the "secondary." Since either winding of the transformer may be connected to the source of energy, these terms are not definite unless the manner of connection is also stated. When referring to the transformer as a separate piece of apparatus the terms "high-tension" winding and "low-tension" winding are used to distinguish the two windings, the high-tension winding being the one with the greater number of turns. When the high-tension winding is connected to the source of supply it is the primary, and the transformer is said to be used as a "step-down" transformer; when the low-tension winding is connected to the source of supply, the high-tension winding is the secondary, and the transformer is said to be used as a "step-up" transformer.

1. CLASSIFICATION

Transformers may be classified according to their operating characteristics, their construction, or the method of cooling.

Constant-potential and Constant-current Transformers. Transformers may be either constant potential, such as are intended to give an approximately constant potential on the secondary side, or constant current, intended to give an approximately constant current on the secondary. Both types are intended to operate on a supply circuit of a constant potential.

Series Transformers are connected in series with the main circuit and receive a variable voltage and current in the primary. The secondary circuit is closed through a path of low impedance, and thus the secondary current will be proportional by the ratio of turns to the load current flowing in the primary or supply circuit. They are generally used to supply low-reading ammeters and wattmeters from circuits carrying very heavy currents.

Auto-Transformers or Compensators, sometimes called single-circuit transformers, consist of one electric circuit interlinked with the magnetic circuit and a tap brought off from some part of the winding. The voltage between this tap and either terminal of the electric circuit will be a fraction of the total voltage, and thus a fractional voltage may be secured from this piece of apparatus. It is customary to proportion the windings on each side of the tap in accordance with the current to be carried. Auto-transformers are generally used where the ratio of voltages is quite near to unity as they can then be constructed with much less copper than the regular transformer. See Article 14 on Auto-transformers.

Potential Regulators are a form of transformer in which the voltage of one member may be varied from zero to a fixed maximum either by changing the direction of the magnetic flux or by changing the phase of the emf of the secondary with respect to that of the primary.

CORE AND SHELL TYPES. Two methods of arranging the electric and magnetic circuits are in use, the corresponding construction being designated as the "core type" or the "shell type." At present a large number of lighting transformers of small and medium capacity are constructed in a manner which is a composite of the core and shell types.

Core Type. The single-phase core-type transformer consists of a single magnetic circuit interlinked with two electric circuits, each consisting of a group of coils as shown in Fig. 1. The three-phase core-type transformer is also shown in Fig. 1.

Shell Type. In the shell type of transformer each electric circuit is interlinked with two magnetic circuits having a common path inside the coils but branching outside of the coils as shown in Fig. 2.

Distributed Core Type (Fig. 2*a*) is a compromise between shell and core type and is much used for small lighting transformers because it economizes in iron and distributes the heat. It consists of the two electric circuits wound concentrically about one central core which divides at the top and bottom into four radiating magnetic circuits surrounding the coils on four sides. It is shown in Fig. 2*a* in plan view.

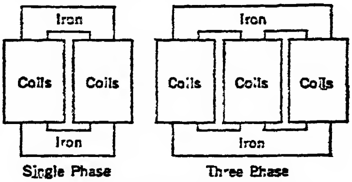

FIG. 1. Core Type Transformer

COMPARISON OF CORE AND SHELL TYPE. The core type of construction is best adapted for high-voltage low-capacity transformers, and the shell type for low-voltage high-capacity transformers. This arises from the fact that the most economical disposition of material in the core type demands a large number of turns and small cross-section of iron while in the shell type a large cross-section of iron and small number of turns may be used to advantage. In the shell type the coils are usually wound in flat "pancakes," this type of construction being particularly well suited to the use of heavy copper ribbon or straps. In the core type the coils usually consist of two or more spools, long in comparison with their diameter. The use of the core type is increasing both in number and size of transformers as it is found possible to arrange the coils so they will better withstand the mechanical strain due to short circuits.

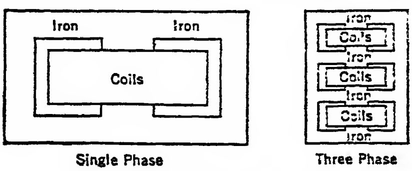

FIG. 2. Shell Type Transformers

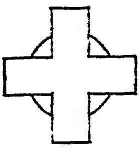

FIG. 2*a*. Distributed Core Type

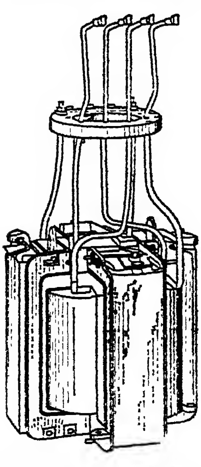

FIG. 3. Core and Coils of Distribution Transformer with Distributed Core

CLASSIFICATION ACCORDING TO METHOD OF COOLING. (See also below.) Transformers may be subdivided into classes in accordance with the method used for dissipating the heat due to their internal losses. As a transformer is a very compact piece of apparatus the problem of carrying away the heat is very important, and various ingenious means have been devised for the purpose.

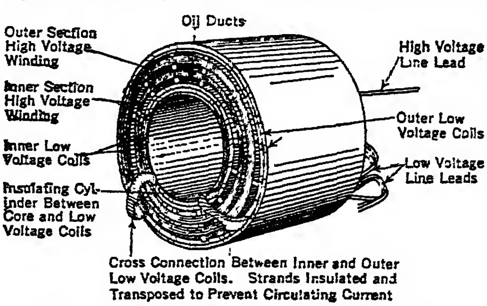

FIG. 4. Details of Coil Construction, Core Type

Air-cooled. This type has no special means of cooling but relies upon the natural circulation of air. It is used only in transformers of very small sizes, such as instrument transformers.

Self-cooled, Oil-immersed. In this type of transformer the core and windings are submerged completely in oil in a tank, and the windings and core are subdivided by ducts in order that the oil may circulate and carry off the heat from the internal parts. The heat is carried to the surface of the tank, which contains the transformer, and from there dissipated to the surrounding air. The tank is specially designed to provide large air-cooling surfaces.

Water-cooled, Oil-immersed. Similar construction to that of the self-cooled type but in addition a coil of pipe carrying running water is submerged in the oil.

Forced-oil-cooled. Transformers artificially cooled by circulation of oil are used when the size is too great for the self-cooled oil type and no cooling water is available. The oil is circulated through external coils or tanks which give a greater cooling surface.

Air-blast Transformers. These are designed with many special air passages through which currents of air are forced by means of a blower, the heat being carried off to the atmosphere in this manner.

Forced-air-cooled, Oil-immersed Transformers have large radiating coils or radiators external to the main tank through which the oil circulates, and these radiators are cooled by a forced circulation of air as in the radiator of an automobile.

METHODS OF RATING. The Standardization Rules of the A.I.E.E. specify that the continuous rating of a transformer is that output in kilovolt-amperes available at the secondary terminals, at rated volts and frequency, without exceeding a temperature rise of 55 deg cent as measured by resistance. In oil-cooled transformers the rise by thermometer should be the same; in air-blast transformers the rise by thermometer may be 60 deg cent.

The iron core of transformers takes a very long time to reach a constant temperature; that of oil-cooled transformers in particular may require from 10 to 12 hours.

2. TRANSFORMER PRINCIPLES
